Richard C. Hallgren, Ph.D., is an assistant professor at Michigan State University. He has written numerous articles and books, including INTERFACE PROJECTS FOR THE TRS-80, published by Prentice-Hall.

INTRODUCTION

The rapid expansion of the electronics industry and their ability to mass produce reliable, large-scale integrated circuits has led to the reality of scientific calculators and multifunction digital watches for under \$20 and "personal computers" starting from \$200. In 1971 the Intel Corporation had the honor of initiating this revolution by introducing the first commercially available microprocessor. While the performance of this device was limited by its relatively slow central processing unit and its use of a 4-bit data bus, its acceptance was so dramatic that within a two-year period the cost of a single unit had dropped from \$200 to under \$20. Today, it is a rare individual who does not have a microprocessor (if not a personal computer) of some type in his or her home.

As I have talked to owners of personal computers, it has become apparent that there is a certain group of individuals who

would like to use their machines as extensively as is possible, both at home and at their place of employment. This inevitably results in the need for interface circuitry to allow the computer to be connected to external devices allowing users to monitor and control their environment. On the basis of the response of readers to several articles that I have written, I have come to the conclusion that there is a great need for a book that covers not only the theory behind interfacing a computer to external devices but also gives a broad selection of interface circuits that can be built and expected to work. What I have attempted to do is to provide you, the reader, with a number if examples of interface circuits ranging from the very simple to the somewhat complicated. I have included software for each circuit and can assure you that both the hardware and the software have not only been tested together but have been used in some practical area of application. The result is a document that explains the theory behind computer interfacing and gives you the choice of either building the circuit as is or modifying it to meet your specific needs. The hardware for these projects was designed and the components selected so that construction and check-out would be a straightforward matter. The circuits have been chosen to offer something of interest and application to a broad range of individuals: the hobbyist, the experimenter, the manager of a manufacturing plant, and the engineer or scientist in a research facility. The intent being to enable people to more fully use the computational and control capabilities of their personal computer in a practical and interesting way.

The book assumes that readers have a fairly good understanding of the commands in Applesoft BASIC, and have written some of their own programs. Since some of the supporting software will be using 6502 machine code, the reader is encouraged to become familiar with the 6502 instruction set. Programing examples using both Applesoft and 6502 machine language have been provided throughout the book. While construction of the circuits is straightforward, it should be understood that a certain amount of experience, and a certain level of expertise is expected. Previous construction of a commercial kit would probably qualify most individuals. So, with all this in mind, let's get started with the job of connecting your Apple II to the outside world.

REVIEW OF DATA TRANSFER FORMATS

BASIC INTERFACE CONCEPTS

Before we get into actual circuit designs, we need to spend some time reviewing basic interface concepts. Even experienced circuit designers should read this section to become familiar with terminology that will be used.

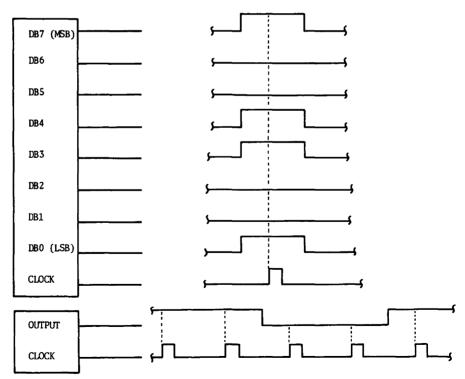

We can define an input/output (I/O) port as a collection of electronic circuits, under the control of the computer, which routes data to and from an external peripheral device. The key words in this definition are data and external. The route by which the data flow to or from the external device is called the port. A line printer is an example of an external device; the computer sends characters to be printed to the printer and, in some cases, the printer sends control signals back to the computer. The pur-

pose of these signals is to regulate the flow of the data. This interaction is called handshaking.

Ports can be constructed so that data are handled in either a serial or a parallel format (Figure 2.1).

Parallel transfer of data involves the mass transfer, at a given point in time, of several bits of data, where the number of bits transferred is usually equal to the word size of the computer. For the Apple II this is equal to 8 bits. In general, the number of bits transferred at one time will be equal to the size of the data bus. For example, if we were working with a Z8000, which has a 16-bit data bus, a parallel transfer would involve 16 bits. When high rates of data transfer are desired, such as data transfer between a computer and a floppy disk, the transfer is usually handled with a parallel format. Computers handle parallel communication rela-

FIGURE 2.1 Comparison of parallel and serial format. The clock impulse is used to signal the external device that the signals are stable. For both examples, the data word being transmitted is binary 10011001.

tively easily and, even though multiconductor cables are required, the total expense is not great because the distance between devices is usually quite short.

Serial transfer of data involves transmitting individual bits of data, one bit at a time. Microcomputers do not normally communicate in a serial format, so there is usually not a single machine language command that facilitates this type of operation. Therefore, we need to add either a software subroutine or a new piece of hardware to accomplish a serial transfer of data. Such an addition results in increased system expense, but gives the capability of transferring data over increased distances at relatively high data rates. The Electronics Industry Association (EIA) RS-232C electrical specification for serial transfer of data is the standard for industrial applications. This specification defines the following voltage levels: A logic level 1 is called a mark and is considered to be any voltage level more negative than -3 volts. A logic level 0 is called a space and is considered to be any voltage level more positive than +3 volts. In general, designers use +12and -12 volt levels for the logic 0 and logic 1 states. In addition to specifying voltage levels, the EIA also defines the standard RS-232C connector to be a 25-pin. D subminiature type (commonly referred as a DB-25). The pin assignments and their functions are listed in Table 2.1.

Before we look at specific examples, we should take a look at the architecture of the 6502 to determine how we can communicate in an orderly manner with several peripheral devices that may be connected to the same data bus and to the same address bus. The Apple II computer uses a 6502 type microprocessor to perform the logical, mathematical, and decision-making operations necessary for high-speed operation of the computer. This microprocessor is an 8-bit device which combines the bus structure of the 6501 microprocessor (16-bit address bus, 8-bit bidirectional data bus, and two interrupts) with an instruction set that includes over 150 different commands. The bidirectional data bus is used to transfer information both to and from the central processing unit. The 16-bit address bus has the capability of uniquely defining 65.536 addressable locations. The 6502 generates several control signals which are used both internally and externally to supervise and manage the flow of information. Since data can only flow in one direction at a time, and since the data are usually

TABLE 2.1 EIA standards for DB-25 connector pin assignments when used for communication between RS-232C systems.

Pin 1	PCND - Protective Ground This is chassis or equipment ground. It may also be tied to signal ground.
Pin 2	TD - Transmit Data This is the serial data from the terminal to the remote receiving equipment. When no data is being sent it is in a marking (1) condition.
Pin 3	RD - Receive Data This is the serial data from the remote equipment which is transmitted to the terminal.
Pin 4	RTS - Request to Send Controls the direction of data transmission. In full- duplex operation an "on" sets transmit mode and an "off" sets non-transmit mode. In half-duplex operation an "on" inhibits the receive mode and an "off" enables it.
Pin 5	CTS - Clear to Send Signal from the modem to the terminal indicating ability to transmit data. An "on" is "Ready" and an "off" is "not ready."
Pin 6	DSR - Data Set Ready Signal from the modem to the terminal. An "on" condition indicates that the modem is ready.
Pin 7	SGND - Signal Ground
Pin 8	CD - Carrier Detect An "on" indicates reception of a carrier from the remote data set; "off" indicates no carrier is being received.
Pin 20	DTR - Data Terminal Ready "'On" connects the communication equipment to the communications channel; "off" disconnects the communications equipment from the communications channel.
Pin 22	RI - Ring Indicator An "on" indicates that a ringing signal is being received on the communications channel.

directed to a specific device or memory location, these control lines provide an essential coordinating function.

Figure 2.2 shows the pin configuration for the 6502. The 6502 belongs to the one-address architectural class of microprocessors; that is, all memory-related instructions refer to a single memory location. The direction of all data transfers is controlled by the READ/WRITE* (R/W*) line. When this line goes low, all data transfers will occur in the direction from the processor to memory. When it goes high, all data transfers will occur in the direction from memory to the processor. The timing of all data transfers is controlled by the system clock. The clock system used by the 6502 is referred to as two-phase; it is most easily thought of as two nonoverlapping square waves. When the microprocessor is reading a data byte from memory, the address of the desired memory location is placed on the address bus during the phase one clock pulse. Information stored in that particular memory location is strobed onto the data bus and into the accumulator

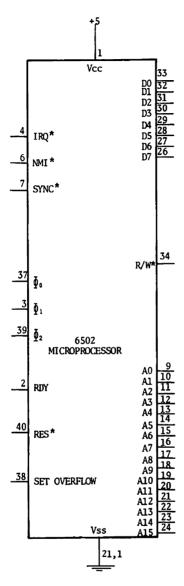

FIGURE 2.2 6502 pin configuration.

during the phase two clock pulse. Data being written to memory is handled by a reversed set of operations.

Fortunately for the individual who wishes to interface the Apple II to external devices, the designer of the computer has provided eight peripheral-board connectors on the mother board. Having these connectors on the mother board allows you to place

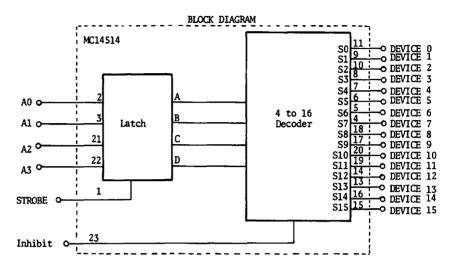

TABLE 2.2 Peripheral I/O location address assignments.

any interface boards that you construct inside the computer's case, and permits you to use the Apple's power supply. The peripheral-board connectors give the hardware designer access to all address, data, and control lines. In addition, certain control and address lines have been decoded to provide the designer with a device select (DS*) signal. What this means is that each peripheral connector has a unique range of address locations that will result in a low output on the DS* line. Since DS* goes low during the phase two clock pulse, it is convenient to use this as a data strobe pulse during either a READ or WRITE operation. Table 2.2 shows the address locations that are assigned to each of the eight peripheral connectors.

Since each peripheral connector can address up to sixteen devices, and since we will not exhaust this capability on any one of the projects that you will be building, I will limit my comments here to one peripheral connector, specifically peripheral I/O location 7. In Chapter 5, however, I will design the digital plotter interface so that it resides in I/O location 5. I will do this so that the high speed A/D converter and the digital plotter can be used to digitize and plot data without having to switch the physical location of the circuit boards. Figure 2.3 shows a simple but effective method for decoding the four least significant bits of the address bus into sixteen unique control lines. For normal operation, the INHIBIT control line would remain low. Upon execution of either a READ or WRITE command, the device control signal (DS*), connected to the STROBE control line, would be used to strobe the current contents of the address bus into the decoder. The decoded output would then be used to indicate to a specific external circuit that the data bus was available for its specific use. In the next section we will see how we can use the R/W* control line to direct the flow of data to and from our interface projects.

FIGURE 2.3 4-16 line address decoder. Each device is selected by a unique combination of the address lines A0-A3.

PARALLEL DATA FORMAT

Transmission and reception of data in a parallel format combines the advantages of high transfer rates and low cost. As mentioned earlier, parallel data transfer involves the mass movement of several bits of data at one time. It becomes a relatively straightforward task to construct both input and output ports since all the control. data, and address lines that we will need are available on the Apple II peripheral I/O connector (see Figure 2.4). Table 2.3 lists the signals appearing on this connector and their functions. Figures 2.5a and 2.5b show examples of practical circuits which could be connected directly to the I/O connector 7, providing one 8-bit input port and one 8-bit latched output port. To transfer data from the accumulator to the latched output port, you need only to perform the BASIC statement POKE-16143.X or the machine language commands LDA #\$X and STA \$C0F1. The microprocessor performs the following bit transfers when you execute either of these commands:

- 1. The device address (C0F1) is strobed onto the address bus.
- 2. The contents of the accumulator (X) are strobed onto the data bus.

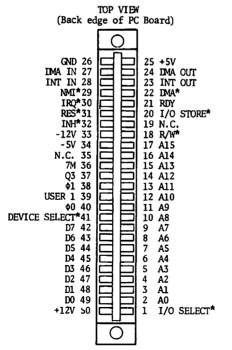

FIGURE 2.4 Output pin configuration for the Apple II peripheral I/O connector. Refer to Table 2.3 for a description of each pin.

ו טל ו	1 +14	Positive 12-Volt Supply

Note: "*" means logical "\$" true input or output.

Since the data are valid for only a few clock cycles (perhaps 500 ns.), a set of clocked flip-flops (IC3 and IC4) are provided so that the data are latched and consequently stable, until the next command to write data to this port is executed. The circuit works in the following manner:

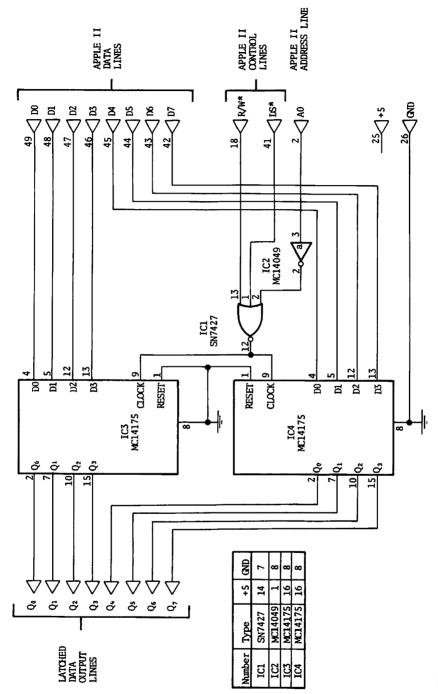

FIGURE 2.5a Circuit diagram of a typical parallel output port. Performing a POKE -16143,16 would cause the DS* and R/W* control lines to go low, address line A0 to go high, and 16₁₀ to be latched into the output register.

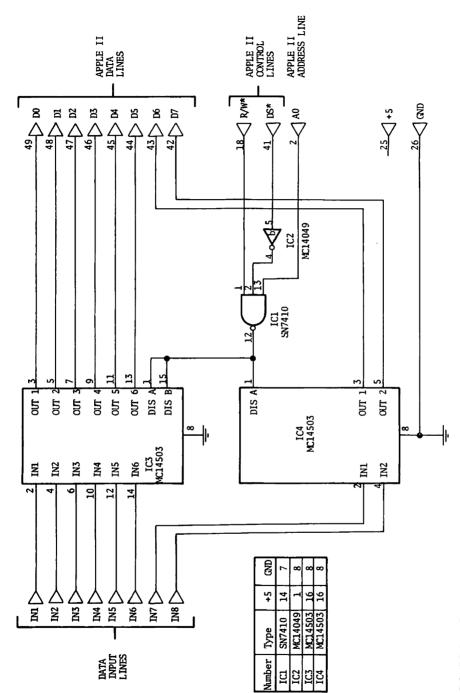

FIGURE 2.5b Circuit diagram of a typical parallel input port. Performing a PEEK (-16143) would cause the DS* control line to go low, the R/W* control line to go high, address line A0 to go high, and the data on the input lines to be transferred into the accumulator.

- Whenever address line A0 is high and the DS* line and the R/W* line are low, there will appear an output strobe pulse on pin 12 of IC1.
- 2. Whenever this strobed output pulse appears, the contents of the data bus will be transferred into the clocked flip-flops, and will appear on the latched data output lines.

External devices transferring data into the computer can be connected directly to the data bus, but to add an additional margin of safety (that is, to help keep you from "smoking" your computer), I have included a 3-state buffer. The 3-state buffer is used as a gate which allows signals from the peripheral device to be placed on the data bus at an appropriate time. To transfer data from an external device into the accumulator, you need only to perform the BASIC statement PEEK(-16143), or the assembly language command LDA \$C0F1. The microprocessor performs the following bit transfers when you execute either of these commands:

- 1. The device address (C0F1) is strobed onto the address bus.
- 2. The contents of the data bus are strobed into the accumulator (A).

The circuit works in the following manner:

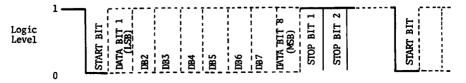

- 1. Whenever address line A0 is high, control line DS* is low, and control line R/W* is high, there will appear a strobe pulse on pin 12 of IC1.
- 2. Whenever this strobed input pulse appears, the 3-state buffer will connect the data input lines to the data bus.

SERIAL DATA FORMAT

When considering a computer interface project involving a fairly large distance between the computer and the device to be interfaced, we begin to realize problems in trying to use a parallel data transfer scheme. First, there is the expense and inconvenience of running a multiconductor cable over long distance. There is also the problem of noise which gets introduced into the data, control, and address lines. While this noise can be reduced with filters, or current level signals can be used, it is often more convenient to

use a serial format for the transmission of control and data bits. With serial transmission, individual bits are transmitted over a pair of wires one bit at a time. The receiving device collects the bits and reconstructs them into a single computer word which, for the Apple II, is equal to 8 bits. Since the computer normally processes data in a parallel format, the transmitting device must perform a parallel-to-serial conversion, and the receiving device must perform a serial-to-parallel conversion. Obviously, the transmission speed and the bit format must be well-defined, and there must be some way to synchronize the serial bit flow so that the receiving device knows where each data word begins. The most common format for serial transmission is called asynchronous-serial. Because it is self-clocking—that is, it contains a special bit pattern that allows the receiving device to know exactly where a new data word begins—the cable connecting a peripheral device with the computer needs to have only two signal lines and one ground line. Figure 2.6a shows the format for the transmission of a data word in an asynchronous-serial format. The START bit, a logic 1 to logic 0 transition, is used to alert the receiving circuitry that a new data word in going to be sent. The receiver waits for one-half of a bit period and then samples the input again. If the input line is still a logic 0, the receiver assumes that it has detected a "real" START bit and not a fluctuation due to noise on the line. The receiving device then waits one bit period and samples the input line to determine whether data bit 1 is a logic 1 or a logic 0. By periodically waiting one bit period and sampling the input line, the remainder of the data bits are obtained. The two STOP bits then signal the receiving device that it has reached the end of the data word. Having transferred the data word into the computer, the device starts looking for the next START bit. Figure 2.6b shows the actual bit pattern that results when the data word 10011101 is transmitted.

FIGURE 2.6a Typical asynchronous-serial bit pattern for the transmission of an 8-bit data word with 2 stop bits.

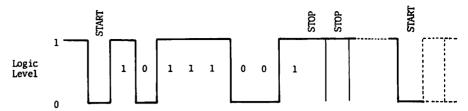

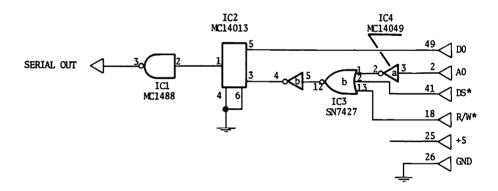

FIGURE 2.6b Logic levels plotted as a function of time during the asynchronous-serial transmission of the 8-bit data word, 10011101₂.

The asynchronous-serial protocol allows the use of either 5,6,7, or 8 data bits along with either 1 or 2 STOP bits. The examples we will be using will be formatted so as to transmit and receive 1 START bit, 8 data bits, and 2 STOP bits. The bit transfer rate can be set to 110, 150, 300, 600, 1200, 2400, 4800, and 9600 bits per second; the actual value depending upon the application.

Figure 2.7 shows a circuit which converts TTL voltage levels to RS232-C voltage levels, and which can be used with the program shown in Listing 2.1 to accomplish a parallel-to-serial output.

FIGURE 2.7 TTL to RS232-C interface.

When a STA \$C0F1 of machine language command is executed, the contents of the least significant bit of the (data bit 0_0) accumulator are latched into the output of the D-type flip-flop (IC2). Figure 2.8 shows a flow chart for the TTL to RS232-C program.

Figure 2.9 shows a circuit which can be used to convert RS232-C voltage levels to TTL levels, and which can be used with the program shown in Listing 2.2 to accomplish a serial-to-parallel conversion. When a LDA \$C0F1 machine language command is executed, the voltage level appearing on the SERIAL IN line will be strobed into data bit D7 of the accumulator. Figure 2.10 shows a flow chart for the RS232-C to TTL program. Timing for both subroutines results in a baud rate of 300 bits per second. The serial output subroutine (Listing 2.1) expects the character which is to be sent to be stored in the accumulator. The serial input subroutine (Listing 2.2) will terminate with the received character displayed on the video monitor. We will put both of these circuits to use in Chapter 5 where we will see how to use the Apple II in serial applications.

SAMPLING THE EXTERNAL WORLD

Now that we have covered some background material relative to the operation of the Apple II computer, we can proceed to the "fun" part of computer operation, the part that involves the evaluation of a need, and the construction of a circuit to meet that need. We will be progressing from examples that are very simple to examples that are somewhat complicated; with the confidence that once you can build and use simple circuits, you will be able to build and use the more complicated ones. In Appendix A I have made a personal appraisal of several construction techniques which you may want to consider; it may be to your advantage to review this material at this time.

STATUS OF A BINARY SIGNAL

For some applications we will want to be able to sample an input port to determine the status or state of an external device. For example, we might want to know if a device was turned on, a valve opened, or a switch closed. Figure 3.1 shows a schematic of a circuit which will allow you to test the state of six switches. When a X=PEEK(-16143) BASIC command is executed, a voltage level, which is a function of whether each individual switch is open or closed, will be strobed into the computer. The variable X can then be decoded to determine the status of each switch. You might use such a circuit to allow external control of a program which is being executed, or to take an action which would be consistent with the state of the switch. The switches might be simple toggle switches mounted on a panel, or they might be relay switches associated with some automated process that you want to monitor. Figure 3.2 shows a flow chart for a BASIC program which will test the status of each switch and display that status on the video display. Listing 3.1 shows the program with comments. This program is intended to be called as a subroutine, and is set up so that if the status has not changed, control will return to the calling routine.

While I have used mechanical toggle switches for this example, the application could be easily extended to the following:

- 1. Water level sensing switches
- 2. Displacement sensing microswitches
- 3. Light sensitive, photoswitches
- 4. Temperature sensitive, bimetallic switches
- 5. Motor relay switches

An advantage of using the computer to sense and respond to the status of a switch lies in its ability to be reprogrammed easily when the application changes.

ANALOG-TO-DIGITAL CONVERSION

Background

There are many applications where we will want to have our computer system "measure" some parameter which varies as a function of time. In most cases, we will be using some type of

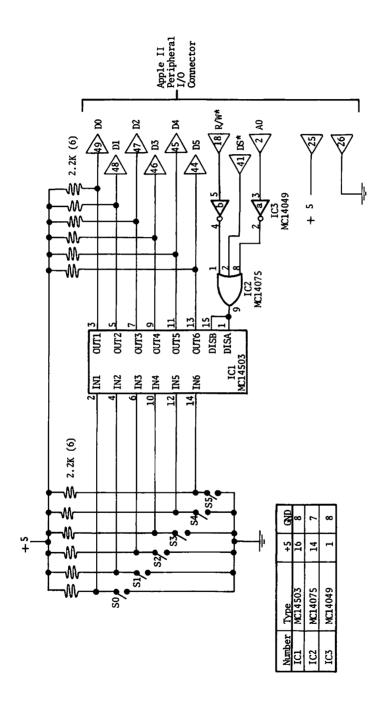

FIGURE 3.1 Schematic of switch status input port.

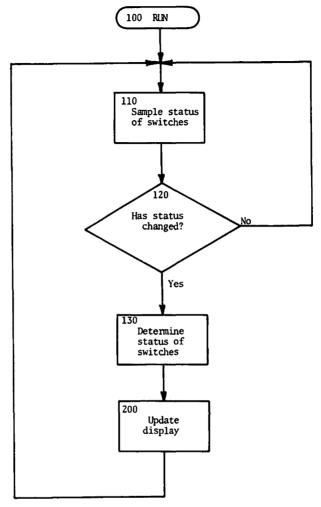

FIGURE 3.2 Flow chart of switch status program.

transducer which takes a physical parameter such as temperature, pressure, strain, or position, and converts it into an electrical voltage or current. While computers are quite proficient when handling binary voltages, they are not directly able to handle the type of analog voltages that will be coming from the transducers we will be using. To resolve this problem we need to build an interface called an analog-to-digital (A/D) converter. Our design criteria will be primarily concerned with determining appropriate values, based on our particular application, for resolution

(dR), relative system error, and sampling frequency (F_s). We will take a look at three examples of A/D converters which are very different in design, using separate and distinct processes to perform the analog-to-digital conversion. I will spend the rest of this section making general comments that will apply to each example, saving specific comments for the individual circuits.

For our purposes, we will define an analog signal as being generally smooth, continuous, and analytical, for example, the output voltage from a pressure transducer, the output voltage from some analytical instrument, or the voltage resulting from some physiological phenomenon such as the electrocardiogram. We shall define a discrete signal as one which is constrained to specific voltage levels, the interval between levels determined by dividing the maximum voltage range (V_{max}) by the number of possible intervals (K). Consequently, any analog voltage which is within the maximum voltage range can be represented as a discrete quantity, the magnitude being equal to some multiple of dR, where dR is defined by Equation 3.1:

$$\frac{dR = V_{\text{max}}}{k} \tag{3.1}$$

Resolution

The function of an A/D converter is to transform an analog quantity into a digital quantity which can be handled by a computer. This transformation usually involves sampling the continuous voltage, representing the voltage as a discrete value, and then formating this quantity so that the computer can process it. An example of a signal represented in both continuous and discrete forms is shown in Figure 3.3. In general, we will assume that Y axis values are dependent upon X axis values such that Y can be expressed as some function of X.

$$Y = F(X) (3.2)$$

Resolution, as we will be using the term, is related to our ability to distinguish between two voltages that have magnitudes which are very close together. The smallest magnitude difference we can detect will define the resolution of our system. For each of the analog-to-digital systems we will discuss, resolution will be equal to the magnitude of a unit change in the least significant digit of the output of the converter.

Relative System Error

Accuracy is related to our ability to determine the actual value of an unknown input voltage. Accuracy will be a function of the

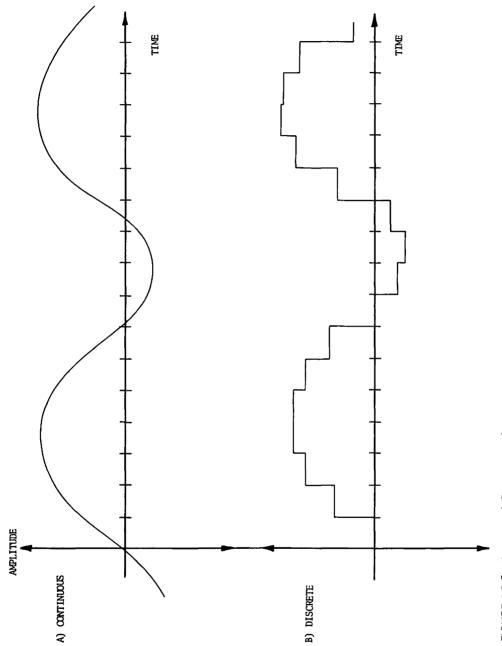

FIGURE 3.3 Continuous and discrete waveforms.

linearity of the system, gain and offset errors, resolution, and magnitude of the signal that we are measuring. In general, the main source of system inaccuracy usually results from the necessity to represent the analog voltage by a discrete quantity. If we assume that this is true for the circuits that we will be building, we can define relative system error as the ratio of system resolution to the magnitude of the voltage being measured. Obviously, for a given system, relative system error will be minimized when the unknown input voltage is equal to the maximum value that the system can handle.

Sampling Theory

Since an A/D converter samples an input signal sequentially with respect to time, the output voltage (Y) can be expressed in the form Y(1), Y(2), and so on. Y(N), where N is equal to the sample number. The rate (F_s) at which we sample the input signal determines the maximum frequency component which can theoretically be detected. The sampling rate can be expressed as a function of the time between samples by the following equation:

$$F_s = 1/dt$$
 samples per second where $dt = [t/N + 1) - t(N)]$ (3.3)

The sampling theorum states that we should sample at a rate which is at least twice the frequency (f_c) of the highest significant frequency component that is present in the waveform which we will be digitizing. In practice, the sampling frequency should be ten times F_c to allow you to reconstruct the complex waveform from the digital data without having to be overimaginative. Remember that you can always throw out data points once you have them if you find that you have sampled at a higher rate than was necessary.

In some applications, you might not be interested in the highest frequency component that was contained in the input signal, but only in lower frequency components. Aliasing, impersonation of a low frequency signal by a high frequency signal, results from choosing a sampling rate that is too low for the frequency components that make up the input signal. Figure 3.4 shows how a relatively high frequency signal and a relatively low frequency signal can share identical sample points, thus making it

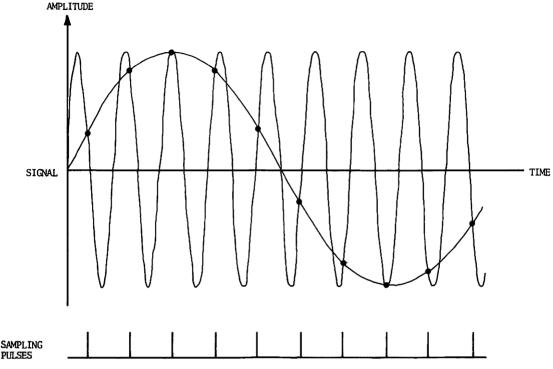

FIGURE 3.4 Aliasing error caused by inadequate sampling rate.

impossible to differentiate between the two signals. For applications where you will be sampling at rates that are less than $2F_c$, you must insert a low pass filter at the input of the A/D converter to limit the frequency content and to ensure faithful reproduction of the input signal.

8-bit, Low-speed A/D Converter

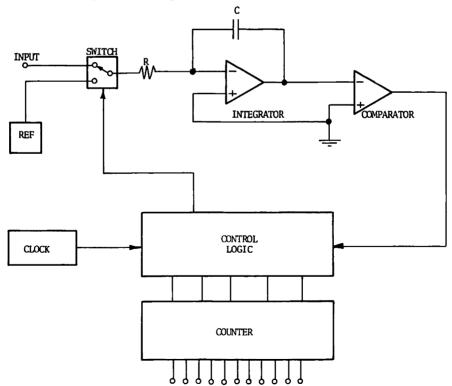

The MC1443 (Motorola Semiconductor Products Inc., Austin, Texas 78721) is a high-performance, low-power, three and one half digit A/D converter combining both linear CMOS and digital CMOS circuitry. This device, when combined with two external resistors and two external capacitors, forms a dual slope A/D converter featuring automatic zero correction and automatic polarity. By using an indirect conversion technique, the dual slope system realizes some of the following positive characteristics:

- 1. Conversion accuracy is independent of component values and the clock frequency.
- 2. Differential linearity is excellent.
- 3. The integration process provides rejection of high-frequency noise and averaging of small voltage changes that may occur during the conversion process.

The main disadvantage to the dual slope technique is that the analog-to-digital conversion process takes a relatively long time, consequently limiting the sampling rate. In spite of this, the device is ideal for digital voltmeters, digital thermometers, and other such devices not requiring sampling rates over 100 samples per second.

Figure 3.5 has been included to help you understand the dual slope conversion process. The actual configuration of the analog circuitry is dependent on the polarity of the input voltage during

FIGURE 3.5 Simplified block diagram for a typical dual slope A/D converter.

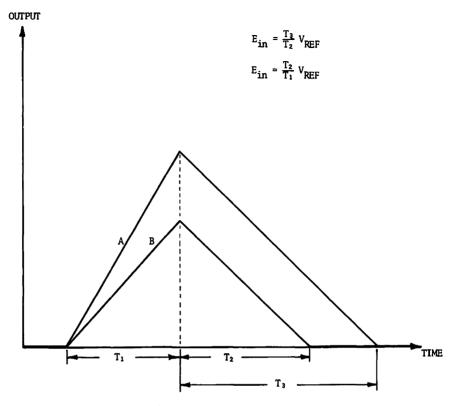

FIGURE 3.6 Integrator output plotted as a function of time for two different input voltages converted by the dual slope process.

the previous conversion cycle, and it is automatically switched by the internal logic circuits. I have chosen to show the analog circuit configuration that would be used when a negative voltage is connected to the input. When performing an A/D conversion, the MC14433 internal control logic first connects the unknown input voltage to the input of an integrator for a fixed period of time determined by an internal clock (See Figure 3.6 for a plot of the integrator output as a function of time.) This results in the voltage across the integrator capacitor increasing to a value which is proportional to the input voltage averaged over the time interval that the input is connected. At the end of this interval, the input to the integrator is switched from the unknown voltage to a reference voltage. The purpose of the reference voltage is to cause the integrator capacitor to discharge at a known rate while a counter

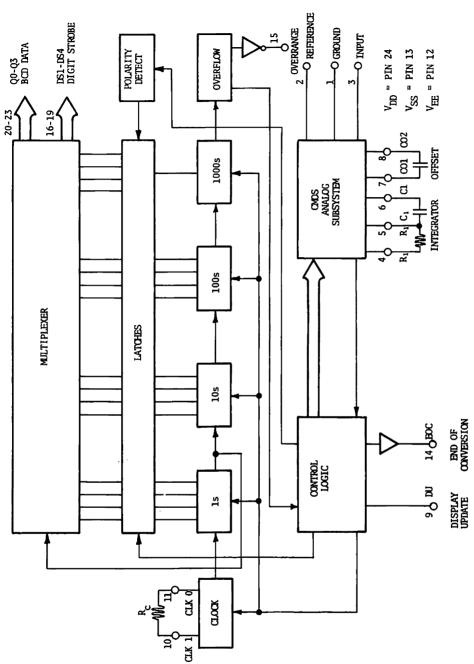

FIGURE 3.7 Block diagram of the Motorola MC 1433 3½ digit A/D converter.

keeps track of the length of time it takes the voltage to return to zero. Note that the count associated with a given input voltage is a function of the reference voltage and the ratio of the time that it takes to charge and discharge the integrator capacitor. In summary, the MC14433 uses a ratiometric measurement scheme that produces an output reading that is a function of the ratio of the unknown input voltage to the reference voltage, where a ratio of 1 equals a count of 1999. It should be obvious to the reader that absolute stability of the reference voltage is necessary to ensure reproducible readings from sample to sample.

Figure 3.7 shows the actual block diagram and Figure 3.8 shows the pin assignment for the MC14433. This integrated circuit operates from standard 5 volt positive (pin 24) and 5 volt negative (pin 12) supplies. (See Appendix C for power supply circuit configurations.) The absolute value of the input voltage

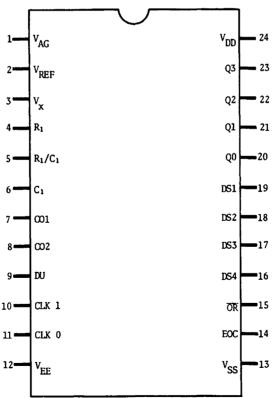

FIGURE 3.8 Pin assignment for the MC14433.

$$V_{\text{out}} = \left[\frac{R_2}{R_1 + R_2}\right] V_{\text{in}}$$

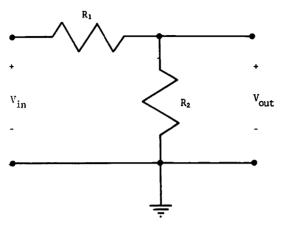

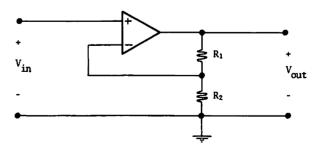

FIGURE 3.9 Simple resistive voltage divider network.

can vary between 0 and 1.999 volts. If the magnitude of the input voltage is greater than the upper limit of 1.999 volts, you can use the voltage divider circuit shown in Figure 3.9 to reduce the voltage to an acceptable value. On the other hand, if the input voltage is less than .2 volts, you will achieve greater accuracy by using a circuit similar to the one shown in Figure 3.10 to increase the magnitude of the input voltage. Appendix B has been in-

FIGURE 3.10 Simple noninverting amplifier.

$$V_{\text{out}} = \left[1 + \frac{R_2}{R_1}\right] V_{\text{in}}$$

cluded to explain the operation of the amplifier circuits such as the one shown in this figure. The frequency of the internal system clock of the MC14433 is controlled by selection of the resistor connected between pins 10 and 11. Figure 3.11 shows typical values for frequency as a function of resistance, and the following equation relates the conversion rate (samples per second) to the clock frequency:

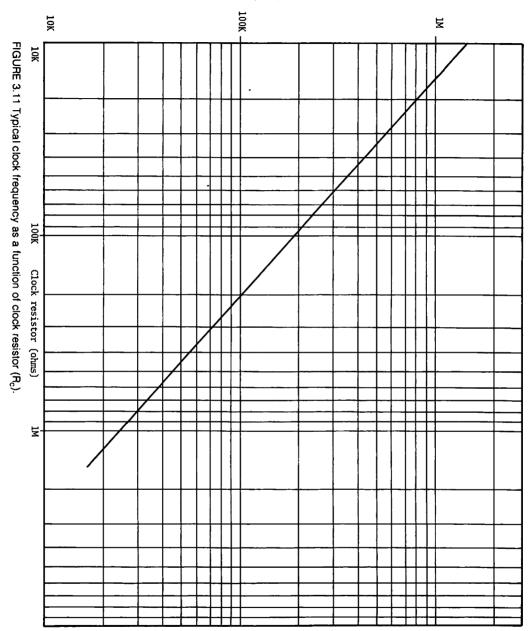

Conversion rate =
$$Clock\ frequency/16,400$$
 (3.4)

Normal operation of MC14433 permits the conversion of an analog signal to a digital signal on a continuous basis, but the results of each conversion are transferred to the output latches only when an appropriate logic pulse is applied to the DISPLAY UPDATE (DU) (pin 9) control line. We can control this transfer of data by providing a positive going pulse to the DU line prior to the ramp-down segment of the conversion cycle. The data that are strobed into the output latches will then be equal to the digital quantity that was obtained from the last A/D conversion.

During the time that the conversion is being performed, the status line, END OF CONVERSION (EOC) (pin 14), is low indicating that the converter is busy. Upon completion of the conversion cycle, this line produces a pulse whose width is equal to one half of the period of the system clock. When this output is wired directly back into the DU input, the result of every conversion is strobed into the output latches. I will use the EOC status line to indicate to the computer when a conversion has been completed and, consequently, when new data has been strobed into the output latches.

The result of an analog-to-digital conversion is contained in the internal output latches in a binary format. However, the data are sent to the external world over the data lines (pins 20 to 23) in a multiplexed, binary coded decimal (BCD) format. 8 bits of information are used to transfer the results of a conversion. The four most significant bits (pins 16 to 19) contain the code for a particular digit, and the four least significant bits (pins 20 to 23) contain the binary value of the digit that is selected. The digit select output lines (pins 16 to 19) go high when the respective digit is selected, and the data lines then contain the value of the selected digit. The digit select timing sequence is arranged so that the most

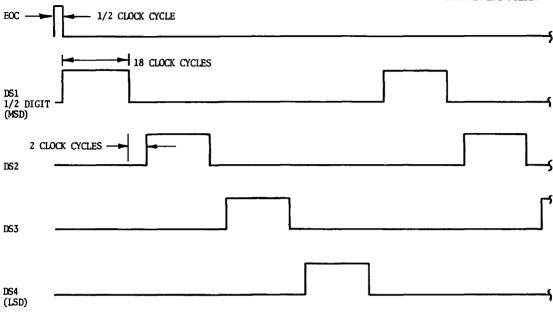

FIGURE 3.12 Digit select timing diagram for the MC14433.

significant digit (MSD) (one half digit) is selected immediately after an EOC pulse. The remaining digits are sequenced as shown in Figure 3.12. When the MSD is multiplexed, the data lines contain not only the value of that digit but also coded information relating to overrange, underrange, and polarity as shown in Table 3.1.

Figure 3.13 shows the low-speed, A/D converter circuit configured for the Apple II. Looking at the upper portion of the figure, you will see the MC14433 A/D converter. The clock resistor (R_c) has been selected and the EOC and DU control lines connected together so that fifteen conversions per second are being performed on a continuous basis. All data and status lines to the Apple II are isolated through the MC14503 three-state buffers (IC7 and IC8). IC4, configured as an R/S flip-flop that is initially reset by the computer, is set by the MC14433 after an alalog-to-digital conversion has been completed. When the Apple II senses this change in status, it starts the decoding and data transfer process. The 6502 processor speed is high enough to enable one conversion to be decoded and stored before another conversion begins. A

TABLE 3.1 Truth table showing the information format on the multiplexed data lines during selection of DS1.

-1 OR	0	0	1	1	3 + 1 MCD	

Notes for Truth Table

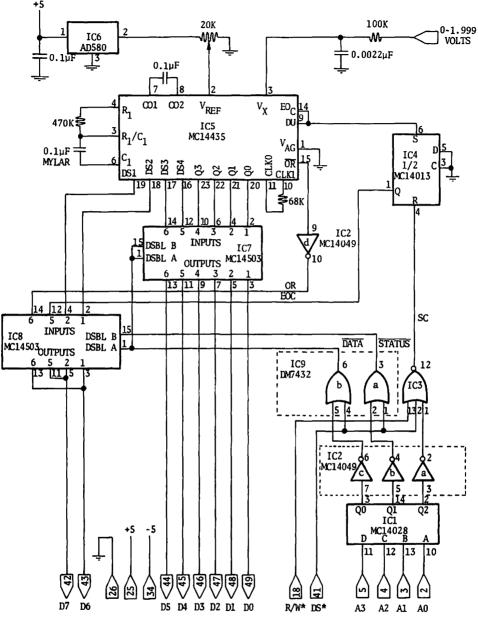

Q3 - 1/2 digit, low for "1", high for "0" Q2 - Polarity: "1" = positive, "0" = negative Q0 - Out of range condition exists if Q0 = 1. When used in conjunction with Q3 the type of out of range condition is indicated, i.e., Q3 = 0 + OR or Q3 = 1 + UR.

The overrange indication (Q3 = 0 and Q0 = 1) occurs when the count is greater than 1999, e.g., 1.999V for a reference of 2.000 V. The underrange indication, useful for autoranging circuits, occurs when the count is less than 180, e.g., 0.180 V for a reference of 2.000 V.

stable reference voltage source is obtained from the output of the Analog Devices AD580 voltage regulator (IC6).

The right lower section of Figure 3.13 shows the control logic that is used to coordinate the transfer of signals to and from the computer. The least significant four bits of the address bus are decoded by IC1 and are used for on-board addressing. By executing an STA \$C0F2 machine language command, the status control line (SC) is forced high, resetting IC4. Performing an LDA \$C0F1 machine language command transfers the end of conversion (EOC) and overrange (OR) status information into the accumulator. Performing an LDA \$C0F1 machine language command transfers the digit select code and the BCD value of the selected digit into the accumulator.

The software portion of the low speed A/D converter has been divided into two parts:

FIGURE 3.13 Schematic diagram of the low-speed A/D converter.

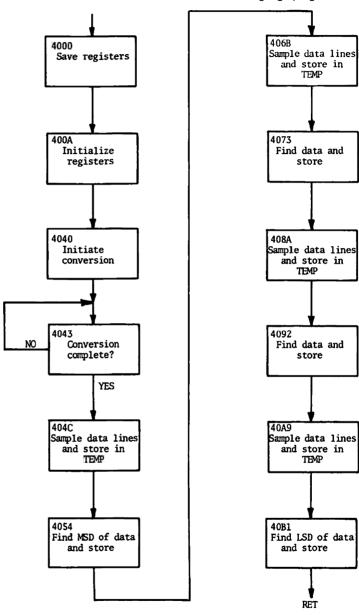

FIGURE 3.14 Flow chart for the machine language program 1.

- 1. A machine language routine was written to control the MC14433, and to provide high-speed transfer of data from the MC14433 to a specific location in computer memory.
- 2. An Applesoft BASIC program was written to take the data in memory and format it into a voltage that can be displayed as a decimal quantity on the video display.

Figure 3.14 shows the flow chart of the machine language program, and Listing 3.2 shows the coded program with comments. Upon entering the subroutine, the end of the conversion (EOC) flip-flop is reset and the program loops until the MC14433 completes the next conversion and sets the flip-flop. The program then samples the data lines and decides whether or not the most significant digit of data was sampled. If it was not, the program continues to sample the data lines until this digit is obtained. Once this digit is found, it is transferred to memory and the program looks for the second digit. After the four digits representing the digitized input voltage have been stored, the program executes an RTS and returns to the BASIC program.

The BASIC routine has the task of calling the machine language routine and assembling the four digits from each conversion back into a single number which is equal to the measured voltage. This program has been written using the CALL command to jump to the machine language routine. A flow chart for the BASIC program is shown in Figure 3.15 and Listing 3.3 shows the coded program. Listing 3.3 has the machine language program included in it as a series of DATA statements that are read in by line 22. You only have to load the BASIC program to get the A/D converter to work. This program performs A/D conversions on a continuous basis, displaying the value of the analog input voltage on the video monitor.

Once the circuitry has been built, you still have the job of finding any errors that may have been made during construction. To assist you in this process, I am including the following checks for you to make:

- 1. The voltage at pin 2 on IC5 should be set to 2.00 volts.
- Using an oscilloscope attached to pin 10 on IC5, you should see a 150,000 Hz distorted square wave varying between +2 and - 2 volts.
- 3. The voltage at pin 1 on IC4 should be equal to +5 volts. Run the following program to repeatedly reset the flip-flop.

```
100 POKE -16142,0
110 FOR I=1 TO 20
120 NEXT I
130 GOTO 100
```

4. After you have loaded the BASIC program, connect a 1.5 volt battery to the input and execute the program. You should see a

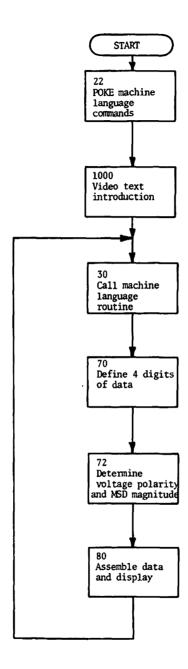

FIGURE 3.15 Flow chart for the BASIC program 1.

video introduction and, after pressing the space bar, you should see the value of the battery voltage (1.54 volts) displayed on the CRT.

The MC14433 circuitry has been set up so that it is performing an analog-to-digital conversion approximately every .067 sec-

onds (fifteen samples per second). Listing 3.4 shows a machine language program that takes a total of 256 samples before returning to the calling routine. Figure 3.16 shows a flow chart for the program. Listing 3.5 shows a BASIC program which calls the machine language routine and then plots the data. Figure 3.17 shows a flow chart for the BASIC program. The BASIC program has the machine language program included in it as a series of DATA statements that are read in by line 24.

Hooking the 1.5 volt battery to the input should give a straight line plot. Figure 3.18 shows a simple resistor, capacitor, and battery combination which can be used to demonstrate the capability of the system. Initially, disconnect the battery and connect the input of the A/D converter across the capacitor. Begin

executing the program. Connect the battery to the circuit. The plot (See Figure 3.19) should show an exponential rise in voltage across the capacitor—exactly what you would expect. Figure 3.20 shows the plot of a .1 Hz sine wave digitized at a sampling rate of fifteen samples per second.

Ten-bit, High-speed A/D Converter

The AD571 (Analog Devices, Norwood, Massachusetts 02062) is a ten-bit, successive-approximation, A/D converter consisting of an internal D/A converter, voltage reference, clock, comparator, approximation register, and output buffers. With this device, an analog voltage can be converted into a quantity represented by 10 binary bits in approximately 25 microseconds, conversion rate not being a function of the magnitude of the input voltage. Figure 3.21 shows the block diagram and pin assignment for the AD571. This integrated circuit can operate from a positive supply voltage

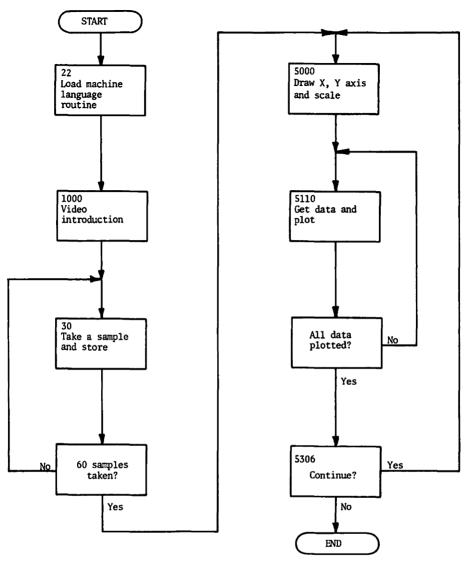

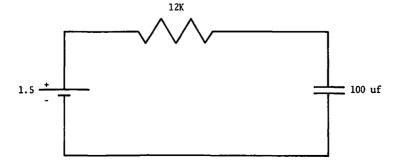

FIGURE 3.17 Flow chart for the BASIC program 2.

FIGURE 3.18 Series RC circuit for low-speed A/D converter demonstration.

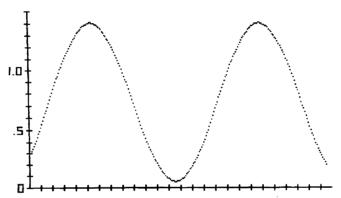

FIGURE 3.20 Sine wave (.1 Hz) digitized at 15 samples per second.

(pin 10) which can be set between + 5 and + 15 volts depending on whether you need TTL or CMOS compatability. The negative supply voltage (pin 12) is intended to be set at -15 volts, but can be set as low as -12 volts if necessary. The AD571 gives the designer the option of being able to configure the internal circuitry for either unipolar (0 to +10 volts) or bipoloar (-5 to +5 volts) operation. If your application involves only positive signals, then the greatest resolution can be realized by operating the circuit in the unipolar mode. Grounding the BIPOLAR OFFSET CONTROL (pin 15) puts the chip in the unipolar mode, while leaving this pin "open" puts the chip in the bipolar mode. Figure 3.22 shows a way to have logic control of pin 15. When operated in the unipolar mode, 0 volts gives an output code of 0000000000 and +10 volts gives an output code of 11111111111. When operated in the bipolar

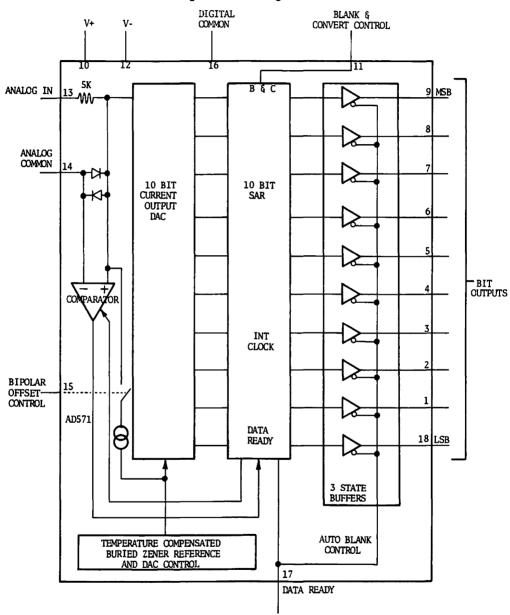

FIGURE 3.21 Block diagram of the Analog Devices AD571 A/D converter.

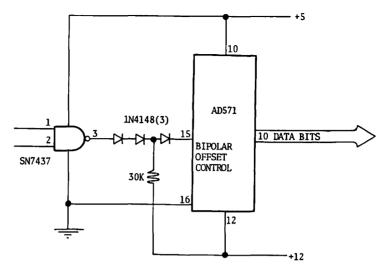

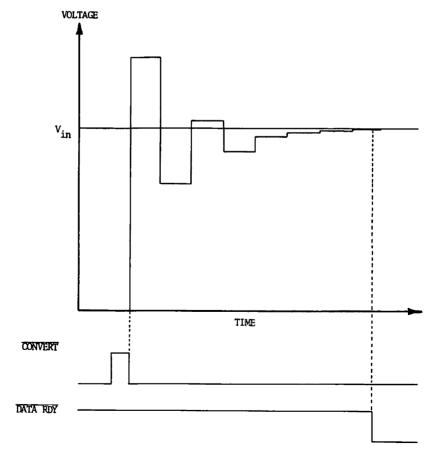

FIGURE 3.22 Bipolar Offset Control controlled by logic gate.

mode, 0 volts gives an output code of 10000000000, -5 volts gives an output code of 0000000000, and +4.99 volts gives an output code of 1111111111. For our application, bipolar operation was desired; consequently, pin 15 was left "open."

The AD571 uses a conversion scheme known as successiveapproximation to achieve the high resolution and speed necessary for some computer applications. Successive-approximation involves comparing the unknown input voltage to a preset series of voltages that are binary fractions of the maximum voltage that may be measured. Initialization of the conversion process is accomplished by providing a pulse to the control line CONVERT*. Upon receipt of the convert pulse, the internal D/A converter is sequenced from its most significant bit to its least significant bit. The internal comparator determines whether the addition of each successively-weighted bit creates a voltage which is greater or less than the input voltage. If the voltage is greater, the bit is turned OFF; if the voltage is less, the bit is left ON. After the sequence is completed, the conversion is complete and the internal successive approximation register contains the 10-bit binary code which represents the input signal. Thus, for a circuit that measures an input varying between 0 and 10.0 volts, the comparisons would be made between voltage levels that varied in 9.766E-3 volt increments (10 volts divided by 1024 discrete levels). When an unknown input voltage is to be converted, the MSB of the D/A

converter's output (½ full scale) is turned ON and the input voltage is compared to 5 volts. If the input voltage is less than 5 volts, the MSB is turned OFF, the next bit (¼ full scale) is turned ON, and the input voltage is compared to 2.5 volts. If the unknown voltage is greater than 2.5 volts, the second bit is left ON, the next bit (¼ full scale) is turned ON, and the input voltage is compared to 3.75 volts. If the unknown voltage is less than 3.75 volts, the third bit is turned OFF, the next bit (¼ full scale) is turned ON, and the input is compared to 3.125 volts. This process continues in order of descending bit weight until all the bits have been tried. The conversion process is thus completed and the 10-bit binary number representing the unknown input voltage is ready to be read by the computer. Figure 3.23 shows the timing relationship between the start of a conversion and the test sequence that we have described above.

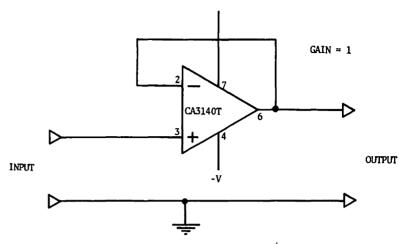

FIGURE 3.24 Noninverting, unity gain, buffer amplifier.

During the time that the conversion is being performed, the status line, DATA READY* (pin 17), goes high indicating that the converter is busy. Upon completion of the conversion, the status line goes low, bringing the three state buffers out of their "open" state and activating the bit output lines.

The typical input resistance of the AD571 is equal to 5000 ohms. Since this is low enough to excessively load some circuits, I would recommend that you use a buffer circuit to provide the necessary impedance matching. If your input voltage approaches the maximum capability of the A/D converter, then the simple unity gain, voltage-follower shown in Figure 3.24 should be adequate. If your input voltage is much less than the maximum the converter is capable of measuring, then the inverting amplifier shown in Figure 3.25 should be used. Notice that the gain of this amplifier configuration is variable, depending upon the ratio of the resistor combinations that are used. Appendix B has been provided to explain the operation of amplifier circuits, and to provide you with enough information so that you can design a specific circuit to satisfy your design requirements, if you should need to do so.

DETERMINING THE RESOLUTION While we have discussed the definition of resolution in an earlier section, I would like to make some additional comments which will help you

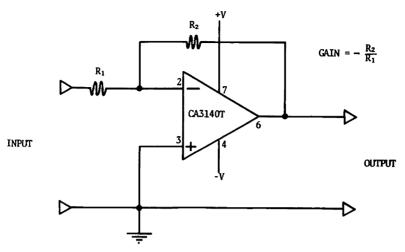

FIGURE 3.25 Inverting, adjustable gain, buffer amplifier.

determine the resolution that your particular application will require. In the process of A/D conversion, we are representing a continuous analog voltage in terms of a certain number of binary bits. We have already stated that the number of binary digits which are available to represent the analog signal is going to determine the resolution of the system, where resolution gives a measure of the converter's ability to distinguish between two voltages separated by some small voltage increment dR. For example, in Figure 3.26 we have the block diagram of a typical 8-bit A/D converter. Functioning correctly, this device will convert an analog input voltage, V_{in}, into a discrete voltage represented by the 8-bit binary number at the output. If a 0 volt signal is represented by a bit configuration equal to 00000000, and a + 10 volt signal is represented by a bit configuration equal to 11111111, then any magnitude of voltage between these extremes will be equal to a multiple of .039 volts (10 volts divided by 256 discrete levels). The converter will by necessity introduce an uncertainty—consequently, an inaccuracy—into the measurement, since the actual input voltage has to be represented by a discrete quantity at the output, and there are only so many bits which are available. It should be easy to see that we should be able to increase the accuracy of the A/D converter by increasing the resolution, that is, by increasing the number of binary output bits which are available to represent the input voltage. For example, if

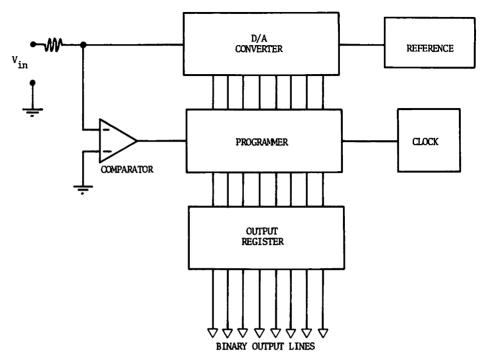

FIGURE 3.26 Block diagram of an 8-bit, successive approximation type A/D converter.

we were using a 10-bit A/D converter, we would expect the device to represent the input voltage as one of 1024 possible values. This would mean that a 0 volt signal would be represented by 0000000000, a +10 volt signal would be represented by 11111111111, and values in between these two extremes would be assigned values in steps of .00977 volts (10 volts divided by 1024 discrete levels). This is obviously an improvement over the 8-bit device.

Since increased resolution usually means increased circuit cost, increased conversion time, and increased memory requirements, we need to wisely choose the number of output bits that will satisfy our particular design requirements without providing excessive capability. How then do we determine the resolution (dR) which we will need to meet the requirements of our application? Suppose we needed to determine the magnitude of the input voltage and be reasonably certain that the apparent magnitude was within 1 percent of the actual magnitude. To achieve this, we would have to have a resolution of at least 1 part in 100. To attain

this resolution, we will need at least 7 binary bits at the output. If both positive and negative quantities are to be represented, the converter will need one extra bit to represent the sign, making a total of 8 bits. While 1 percent sounds pretty good, remember that this is in reference to the maximum voltage that the converter can handle; this means that for a maximum input voltage of 10 volts, you will be able to distinguish signals that are .1 volt apart. If the input voltage is varying between 0 and +1 volt, you still will have a resolution equal to .1 volt, but your accuracy will have decreased to 10 percent (1/.1). Keep in mind that for this discussion, I am assuming that the primary source of inaccuracy in our system is due to a lack of resolution. To determine a measure of your system's ability to differentiate between the magnitude of two voltages, follow these steps:

- 1. Determine the magnitude of the signal that you will be measuring.
- 2. Determine the maximum resolution of your system by dividing the magnitude of the output signal which corresponds to all 1's, by the number of discrete voltage steps which the system is capable of providing. Do not count sign bits.
- 3. Divide the quantity from Step 2 by the quantity from Step 1 and multiply by 100 to get the accuracy expressed in percent.

You should realize that in Step 1 you were concerned with the magnitude of the signal that you would be measuring, not the magnitude of the signal that you were capable of measuring. The truncating and rounding procedure that the A/D converter performs to get the input signal to fall into predetermined voltage slots has the effect of causing the accuracy to vary as a function of the magnitude of the input signal (even though resolution remains constant). For this reason, you should always be aware of the magnitude of the signal which you will be measuring; often, the system you choose will have to be a compromise between accuracy and dynamic range.

Figure 3.27 shows a schematic diagram of a high-speed A/D converter for the Apple II, and Figure 3.28 shows a schematic diagram of a crystal controlled time base oscillator which we will be using to determine the sampling rate. IC1 is an analog multiplexer which is used to select one of eight possible input signals. Control of input signal selection is accomplished by latching a given bit pattern at the output pins of the quad type D flip-flop

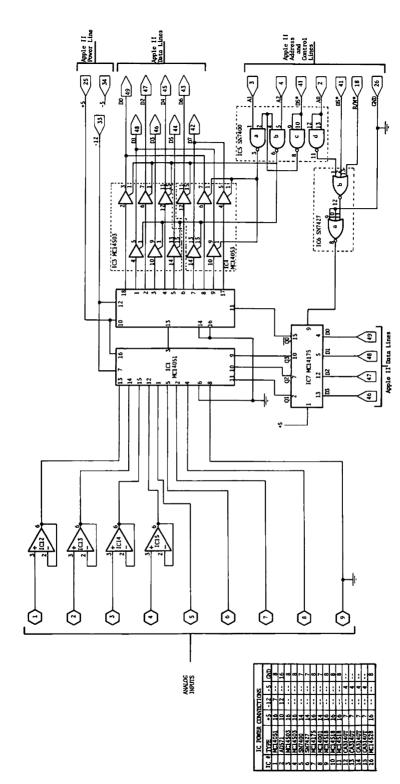

FIGURE 3.27 High-speed A/D converter for the Apple II.

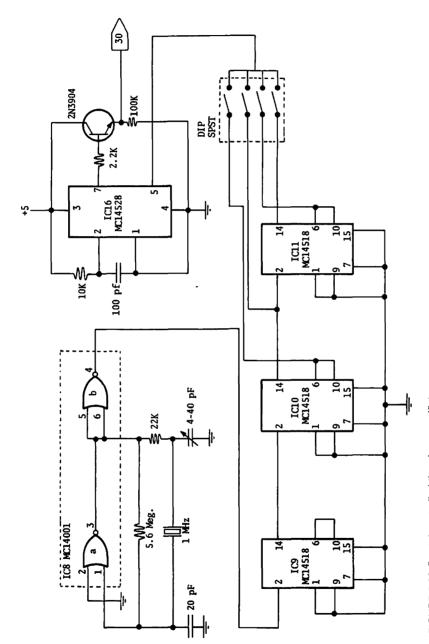

FIGURE 3.28 Crystal-controlled time base oscillator.

(IC7). You should notice that one of the lines from the flip-flop is connected to the A/D converter. This is the control line (CONVERT*), discussed earlier in the overview of the AD571 A/D converter (IC2), which is used to signal that a conversion is to begin. Data lines D0, D1, and D2 then control the selection of the analog input signal, and D3 controls the initiation of the conversion process. If you executed the following BASIC commands, you would convert the analog signal present at input 2 into a digital quantity.

100 POKE - 16143,09 110 POKE - 16143.01

IC12, IC13, IC14, and IC15 are operational amplifiers which are configured as unity gain, noninverting buffers. They are used to isolate an input signal from the input of the AD571 to avoid problems associated with the relatively low input resistance of this device. Four unbuffered inputs are also provided for input signals which do not need to be isolated (having a low value of series output resistance), or which require an additional stage of amplification.

All the data and status lines to the Apple II have been isolated through use of the MC14503 three-state buffers (IC3 and IC4). Since the Apple II is an eight-bit machine, the 10 bits from the AD571 are transferred to memory in a two-step operation. The DATA RDY* line and the two most significant bits are read into the machine through the use of an LDA \$C0F2 machine language command. When the AD571 signals the Apple II that a conversion has been completed (by dropping DATA RDY* to 0 volts), the following sequence of operations should be performed:

- 1. The most significant two bits of data (appearing on D0 and D1 of the data bus) should be stored in memory.
- The least significant eight bits should be transferred into the computer through the use of an LDA \$C0F4 machine language command and stored in memory.
- 3. The Apple II should then either process the data or return to gather more data.

IC8 and the 1 MHz crystal provide a stable pulse train which is used to determine the sampling frequency. IC9, IC10, and IC11 divide the 1 MHz pulse train by multiples of ten so that sampling rates of 1, 10, 100, and 1000 samples per second can be obtained. IC16 is a monostable multivibrator which is used to provide an inverted output pulse, width being independent of the output frequency, to the Apple II I/O interrupt input. The 2N3904 transistor is configured as an emitter follower to provide the current drive requirements necessary to drive the interrupt line.

Once you have constructed the interface, connect it to the Apple II and perform the following tests to make sure that it is working correctly:

 If you execute the following BASIC statements, pin 7 and pin 2 on IC7 should go to +5 volts. Pin 10 and pin 15 should remain at 0 volts.

```
100 POKE - 16143.09
```

2. If you execute the following BASIC statements, pin 2 on IC7 should go to 0 volts. Pin 7 should remain at +5 volts. Pin 10 and pin 15 should remain at 0 volts.

```
100 POKE - 16143.01
```

3. If you now apply an analog signal to input IN1, you should see that signal at the output (pin 3) of the multiplexer (IC1).

If you have an oscilloscope, you can perform the following tests and adjustments:

 If you execute the following BASIC statements, you should see the DATA RDY* line periodically go from 0 to +5 volts.

```
100 POKE - 16143,09
110 POKE - 16143,01
140 FOR I= 1 TO 100
142 NEXT I
150 GOTO 100
```

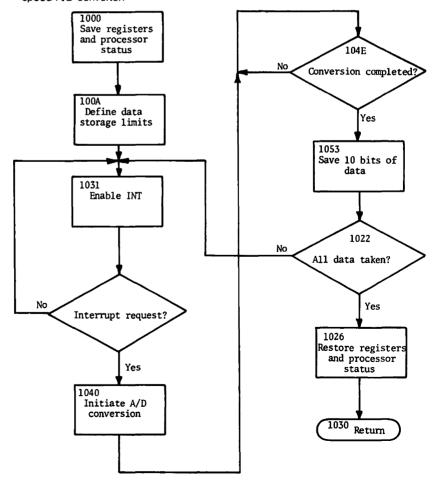

- 2. Adjust the 4-40 pf trimmer capacitor in the crystal oscillator until the output of IC8 is equal to 1 MHz. The IRQ* line should reflect the sampling frequency that you have selected.
- 3. Measure the pulse width of the output of IC16. It should be approximately equal to .1 milliseconds.

The software portion of the high speed A/D converter interface was handled in two parts:

- 1. A routine written in Applesoft BASIC takes the binary representation of the analog data and converts it into a decimal number which then can be displayed, or stored for future reference.
- 2. A machine language routine which was written to control the AD571 and to provide high speed transfer of the binary data into the Apple II.

Figure 3.29 shows a flow chart for the machine language routine, and Listing 3.6 gives the actual program with comments. Upon entering the subroutine, all necessary registers are saved to allow

a successful return to the BASIC calling routine. The program then defines the data storage space and initializes the system I/O bus. The interrupt request line is then activated and the program loops until an interrupt request is made. The request for an interrupt comes from the output of the crystal time base oscillator, the frequency being dependent upon the position of switch S1. After

receiving an interrupt request, the program initiates an A/D conversion, and waits until the AD571 signals that the conversion is completed. The 10 data bits are then stored in memory and the program tests to see if the data storage is filled. If all the data storage has been filled, the program restores all the necessary registers and returns to the BASIC calling routine. If all the data storage has not been filled, the program returns to activate the interrupt system and to take more data.

Figure 3.30 shows a flow chart for the BASIC program, and Listing 3.7 gives the actual program with comments. The BASIC routine first loads the machine language routine by using the READ and POKE statements. Then the machine language routine is called to obtain a block of digitized analog data. When the

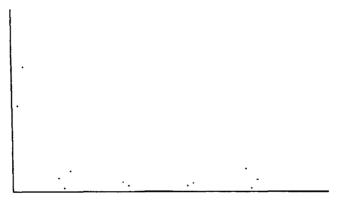

FIGURE 3.32b 100 Hz digitized at 1000 samples per second (*5).

DIGITAL-TO-ANALOG CONVERSION

Digital-to-analog (D/A) converters are devices that take a digital input—usually from the data bus of a computer—and convert it into an analog signal. While the analog signal is often thought of as being a continuous quantity, the output of the D/A converter will actually consist of a series of discrete and easily measurable voltages. Resolution, the voltage difference between steps, will depend upon the number of bits that the D/A converter can handle.

The Analog Devices AD558 DACPORT is an 8-bit digital-toanalog converter that includes a precision voltage reference, a microprocessor interface, a data latch, and an output amplifier all on a single monolithic chip. Thin film silicon-chromium resistors are used in a current-driven ladder to provide an analog voltage that is stable over a large temperature range. Figure 4.1

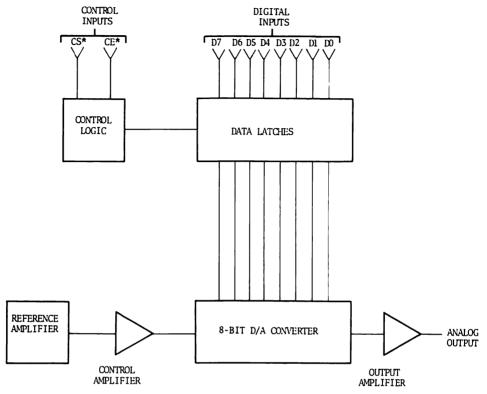

FIGURE 4.1 Functional block diagram of the AD558.

shows a functional block diagram of the AD558. The data latch is connected to the computer data bus, data being accepted when both control inputs, CE* and CS*, are low. When either control input returns high, the 8-bit data word is latched and the analog output is unaffected by further activity on the data lines. For a maximum output voltage of 2.56 volts, the resolution of the converter will be equal to 0.1 volts; that is, a change in the least significant digit will result in .01 volt change in the output voltage.

Figure 4.2 shows the schematic diagram for a D/A converter interface for the Apple II. Data is strobed into the converter by writing data to the appropriate I/O slot. The analog output will then remain stable until new data is written.

After you have finished building the interface, perform the following tests to make sure that it is working correctly:

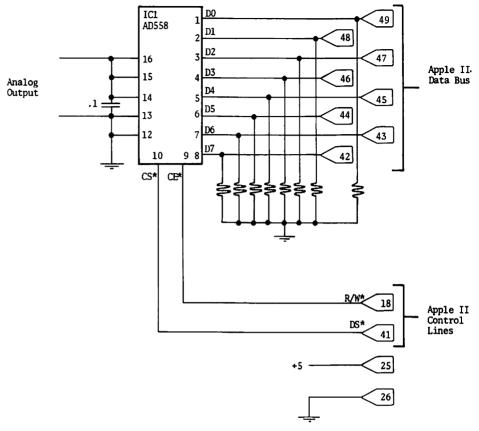

FIGURE 4.2 Interface schematic for the AD558 D/A converter.

If you execute the following BASIC statements, you should see the analog output ramp from 0 volts to 2.55 volts.

110 FOR I= 0 TO 255 120 POKE - 16143,I 130 NEXT I 199 END

Digital-to-analog converters are commonly used in digitally-controlled power supplies for automated test equipment, digital generation of analog waveforms, and digital control of automatic process control systems. I will present examples of two automatic test equipment systems that might be constructed to perform quality control testing in a manufacturing facility.

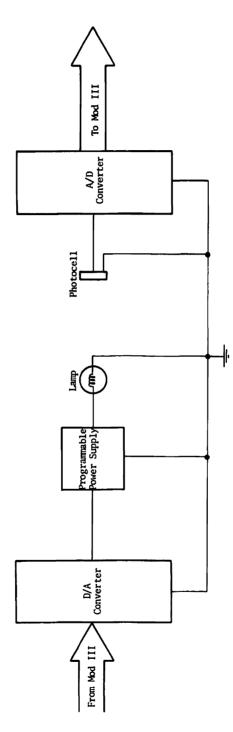

FIGURE 4.3 Block diagram of proposed testing arrangement.

The first example involves cycling an incandescent lamp through a number of voltages to determine if the lamp intensity is acceptably high. The lamp might be used in a simple colorimeter for a chemistry laboratory, and its intensity may need to be above a certain level to ensure reliable operation. Since checking each lamp could be very time consuming, it would be desirable to have the computer automatically increase the lamp voltage and record the lamp intensity at each voltage. At the end of the test, the computer could then make a decision regarding the acceptability of the lamp. The output of the AD558 is already buffered, but by itself cannot provide enough current to drive an incandescent lamp. What we will do is build a voltage programmable power supply, one whose output voltage is some multiple of the input voltage supplied by the A/D converter.

Figure 4.3 shows a block diagram of the proposed testing arrangement. The data bus from the Apple II will supply a binary number that will be converted by the D/A converter into an analog voltage. This voltage will then be used to control the lamp voltage. Lamp intensity will be monitored by a photocell connected to the high speed A/D converter which we discussed in Chapter 3. Figure 4.4 shows a schematic diagram of the programmable power supply. Figure 4.5 shows a flow chart for an Applesoft BASIC program to cycle the lamp voltage from 0 to 2.0 volts. Listing 4.1 shows the actual program with comments.

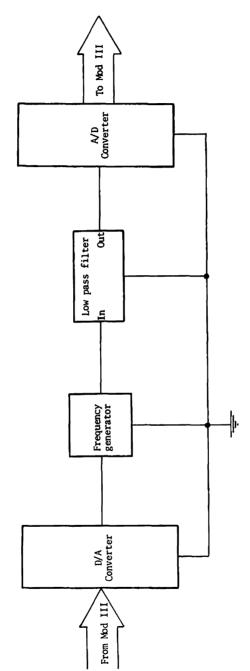

FIGURE 4.6 Block diagram for low-pass filter testing arrangement.

The second example involves testing the frequency response of a low pass filter. We will use the D/A converter to directly control the output frequency of a B&K 3010 Function Generator (Dynascan Corporation, 6460 W. Cortland Street, Chicago, Illinois 60635). This instrument has an input jack which allows an external voltage to directly control its output frequency. Figure 4.6 shows a block diagram of the proposed testing arrangement. Again, the data bus from the Apple II will supply a binary number which will be converted by the D/A converter into an analog voltage. This voltage will then be used to control the frequency of the function generator. The output of the low pass filter could be monitored by connecting it to the high speed A/D converter, and the computer could determine if the 3db cutoff frequency is within acceptable limits.

For both of the examples that we have looked at, the goal was to reduce the amount of personnel time required to perform a routine test operation. This was accomplished through the use of a computer-controlled test protocol.

UTILIZATION OF THE APPLE II IN SERIAL APPLICATIONS

HIGH RESOLUTION DIGITAL PLOTTING

Utilization of personal computers, such as the Apple II, in business and research applications has met with considerable success. Not only do they function as computational tools but, when used in conjunction with peripheral devices, they can perform complex functions at reduced expense. The research laboratory often deals with complex, time-dependent waveforms. This type of data can be easily digitized (see Chapter 3) and analyzed (see Chapter 8), but a major problem arises when a permanent copy of the data is required. Printing a column of numbers does little to convey to the researcher the nature of the data, especially several months after the data are taken. Plotting with a terminal such as the Decwriter II is possible, but lacks the necessary resolution for

many applications. The HIPLOT Digital Plotter, manufactured by Houston Instruments, gives the researcher a cost effective means of obtaining quality digital plots. The plotter accepts an $8\frac{1}{2} \times 11$ inch sheet of paper and allows plotting within a 7×10 inch boundary. Reversible stepper motors are used to give bidirectional steps of either 200 or 100 steps per inch, amounting to a resolution of .005 or .01 inches per step respectively. The plotter comes with a standard RS-232C serial interface, so interfacing it to the computer is a relatively straightforward task.

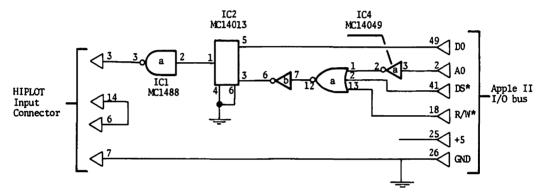

FIGURE 5.1 HIPLOT and Apple II interface connections.

We have already discussed the serial data format in Chapter 2, and we have examined the necessary hardware (see Figure 2.9) and software (see Listing 2.1) to implement a TTL to RS232-C conversion. If you have not already built this circuit, you should do so now. Since we will be using the power supply in the Apple II, you will not need to provide any additional voltages. Once you have constructed the interface, connect it to the plotter as shown in Figure 5.1 and insert the circuit board into I/O slot 5. Perform the following tests to make sure that it is working correctly:

1. If you execute the following BASIC statement the output of IC1 should go to +10 volts.

POKE - 16175.0

2. If you execute the following BASIC statement the output of IC1 should go to -10 volts.

POKE - 16175.1

3. Load and execute the BASIC program shown in Listing 5.1. If everything is working correctly, the plotter pen should begin mov-

ing toward the right hand side of the platen. If you execute the program and nothing happens, you should borrow an oscilloscope and check both the bit pattern and the bit spacing of the serial data. Figure 5.2 shows the bit pattern and spacing that should be obtained.

Being able to accomplish the transfer of information in an RS232-C format is only the first step towards using the plotter. The HIPLOT consists of two stepper motors which control the X,Y position of the plotter pen. Control of the pen position, and all other plotter functions, is accomplished by sending specific control characters to the device. Figure 5.3 shows the axis system for the plotter pen, and Table 5.1 shows the character that produces an increment of the pen along the given vector. Also included are

FIGURE 5.2 Bit pattern and spacing of RS232-C output from the demonstration program

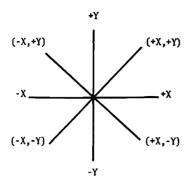

FIGURE 5.3 HIPLOT vector notations.

TABLE 5.1 HIPLOT command characters.

Pen down	у	9210

the characters that produce control functions such as PEN UP. Since the plotter comes without any software, it is necessary to write subroutines to generate an axis system, to lable the axis, and to plot the data.

Listing 5.2 shows a program which provides some of these capabilities. Figure 5.4 shows a flow chart for the BASIC program. This program draws an X,Y axis system, lables the system with numeric characters, and plots an exponential increase in voltage as a function of time. Figure 5.5 shows a series of plots taken for increasing values of the time constant. The software was written so that the entire plot could be scaled to different dimensions. Figure 5.6 shows the maximum range of plot size. It should be obvious to the reader that the program will most likely have to be modified to meet the requirements of the specific application. The program shown in Listing 5.2 was written in a very general sense

FIGURE 5.4 Flow chart for the digital plotter program.

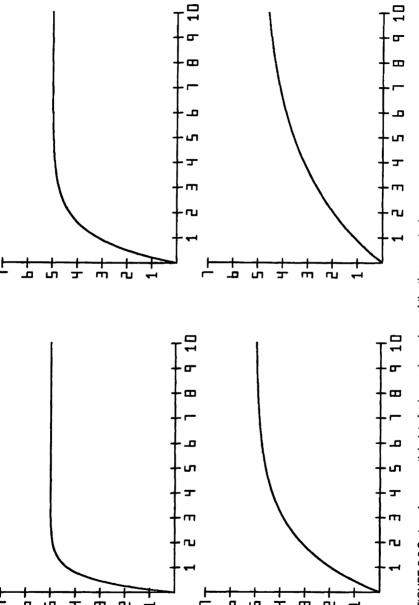

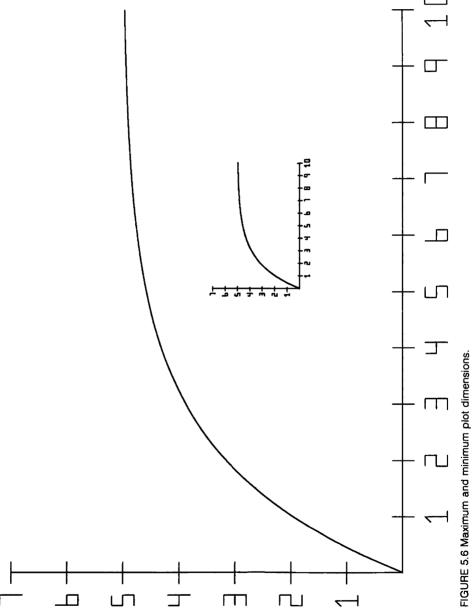

FIGURE 5.5 Series of exponential plots for increasing values of the time constant.

to make it easier for the reader to follow. Consequently, a significant increase in plotting speed can be realized by reducing the number of subroutine calls and keeping the software compacted as much as is possible.

Suppose we would like to plot some of the data that we digitized with the high speed A/D converter and stored on disk back in Chapter 3. Listing 5.3 shows a program which will take the stored data and plot it on the digital plotter. Figure 5.7 shows a plot of a sine wave plotted at both the maximum and minimum plot size. The frequency of the sine wave was approximately 10 Hz. You should be aware that the horizontal scale (for a sampling rate of 1000 samples per second) is such that one period of a 20 Hz sine would occupy one inch. Figure 5.8 shows a plot of digitized music which was playing on the radio while I wrote this. Note that it is very difficult to say much about the frequency content of the music from the plot. When you get to Chapter 8, I will show you how you can analyze data similar to this and come to some conclusions about the frequency spectrum.

LISTING 5.3 BASIC program for plotting data stored on a disc.

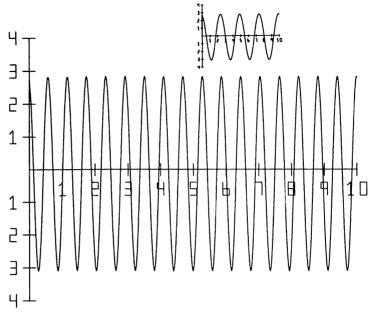

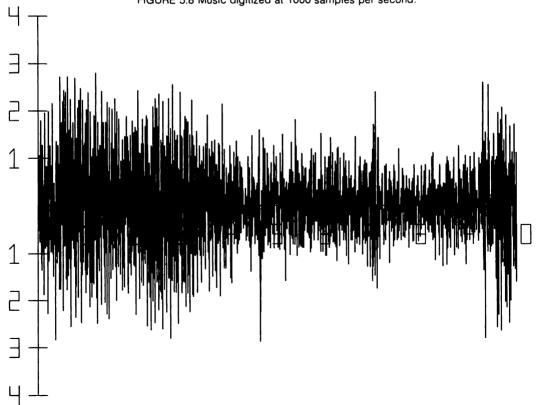

FIGURE 5.7 Sine wave (10 Hz) digitized at 1000 samples per second.

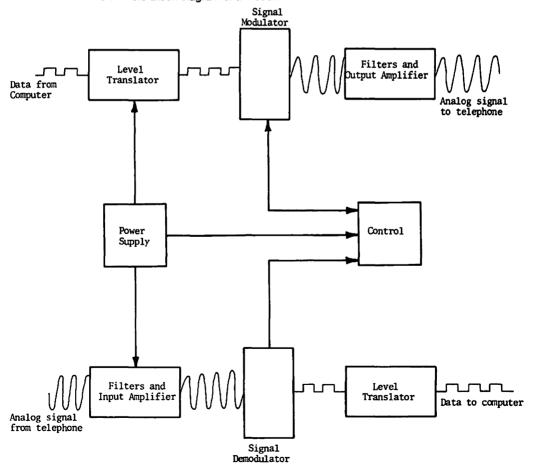

VIDEO TERMINAL

There will be times when you will want to use your Apple II as a video terminal to connect into a large, host computer network. Networks that provide a message retrieval system have been around for quite a while, and we are now beginning to see a proliferation of information services which provide local, national, and international news, weather, sports, and investment-related topics. In the future, you will probably have access to information suppliers dealing with banking, car rental, classified ads, and reservation services. Individuals usually have access to one of these networks through the use of a modem connected between a video terminal and their telephone. A modem is a device which performs two basic functions (see Figure 5.9):

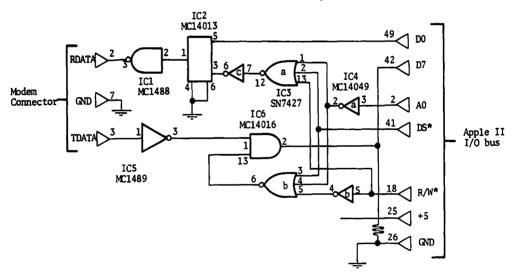

FIGURE 5.9 Block diagram of a modem.

- It accepts digital input from a computer and converts the pulses into analog-frequency signals for transmission over the telephone lines.
- 2. It converts analog-frequency signals from the telephone into digital signals which the computer can process.

Modems that transmit information at 300 bits per second are readily available through a multitude of suppliers for under \$200. You can use the Apple II as a video terminal by building a bidirectional serial interface and writing some software. You could accomplish the same thing by buying a commercial serial interface board, but you can save a few dollars by building your own. You should realize that my approach minimizes hardware and maximizes software, thus saving money at the expense of versatility. Figure 5.10 shows the hardware that will be needed, and the connections that will need to be made to the Apple II and to the

FIGURE 5.10 Video terminal interface circuit and system connections.

modem. You should recognize the circuits as ones that were developed and described in Chapter 2. Once you have constructed the interface and made the interconnections, perform the following tests to make sure that everything is working correctly:

1. If you execute the following BASIC statement the output of IC1 should go to +10 volts.

POKE - 16143.0

2. If you execute the following BASIC statement the output of IC1 should go to -10 volts.

POKE - 16143,1

3. If you execute the following BASIC statements the number which will be displayed on the video monitor should change from a 1 to a 0 when you apply +5 volts to the SERIAL INPUT line.

100K=PEEK (-16143) 110 IF K<128 THEN PRINT "0" 120 IF K>128 THEN PRINT "1" 130 GOTO 100

Listing 5.4 shows the machine language program (see Figure 5.11 for the program flow chart) which allows the Apple II to transmit and receive serial data at 300 bits per second. Listing 5.5 shows the program converted over to a series of BASIC statements.

I will describe the startup procedure that I use for interacting with the university computer system. Since operating systems will differ from location to location, this should be used as an example only.

1. Load and execute the BASIC program.

- 2. Dial up the computer facility, listen for the carrier tone, and insert the handset into the modem (this assumes that you have not purchased a direct-connect modem).
- 3. Press the RETURN key. If the host does not respond, press the RETURN key again.
- 4. Once the host responds, sign on in the normal way.

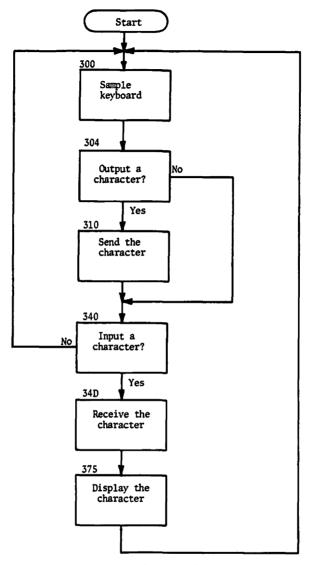

FIGURE 5.11 Video terminal program flow chart.

- 5. Limit the right hand margin to 38 characters to prevent losing data. Double the delay time before printing is resumed after a line feed and a carriage return to avoid losing characters.
- 6. To abort an operation, press the ESC key.

LISTING 5.5 The machine language program in Listing 5.4 incorporated into a BASIC program.

BIOFEEDBACK

Have you ever thought about the number of complex operations that your body is required to perform in the course of a "normal" day of activity? While we often take for granted our ability to perform complex, coordinated muscular activity, this ability results from years of trial-and-error type training. An infant has very little muscular control over its body, and it develops this control by constantly practicing. Most of us have observed a young child learning how to walk; repetitiously standing, taking a few steps, and falling down.

The human brain is composed of billions of specialized cells called neurons. Neurons are designed to transmit information between peripheral sensory receptors and the brain, to analize this information, and to transmit commands, if necessary, back to muscles. For example, when you touch an object, there are sen-

sory receptors in the skin that send the brain coded information related to the temperature of the object. The brain then processes the information and decides what course of action should be taken. Coded information is then sent to the muscles in the hand and arm. The possible result is that the hand may be jerked back from a very hot object, or left in place if the object is cool.

The body is equipped with many similar neuromuscular pathways that never get developed because there is no common use for them. It is no big trick to learn how to wiggle your ears; you just spend some time in front of a mirror teaching yourself which nerves are connected to that particular set of muscles. The normal process of learning requires that feedback accompany the behavior pattern that is being established. That is, you normally expect to see, hear, or feel the results of a particular action. It is difficult to learn how to play the violin if you are deaf. The normal learning experience requires that auditory feedback accompany manipulation of the bow.

Many functions of the body, such as heart rate and skin temperture—long thought to be under exclusive control of the autonomic nervous system—have been found to be controllable. Training involuntary muscles is normally not possible, because we lack a natural feedback path to tell us how we are affecting the system. However, with the aid of sensitive electronic equipment, physiological changes that a person is normally incapable of sensing can be altered and controlled. Thus, the term biofeedback is used when a biological process is measured, and the results of the measurement are fed back to the individual. Through a training experience, the individual can learn to control phenomena such as heart rate and skin temperature.

SKIN TEMPERATURE

Heat is produced in the human body by muscular exercise, assimilation of food, and all the processes that contribute to the basal metabolic rate. Heat is lost to the surroundings through radiation, conduction, and vaporization of water in the nasal passages, and from the skin. Humans—and vertebrates in general—have multiple mechanisms for regulating heat loss so that the body remains at an almost constant temperature under

normal conditions. One of the primary mechanisms for heat regulation is through control of skin temperature. Skin temperature is controlled by regulating the amount of blood that is allowed to flow to the skin. Cold hands and feet are a common phenomena resulting from peripheral vasoconstriction, resulting from a sympathetic nervous system command to contract the smooth muscles lining peripheral blood vessels, thus reducing blood circulation and skin temperature at the extremities and conserving heat.

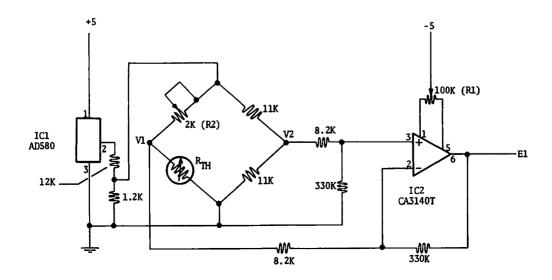

Peripheral skin temperature is influenced by a number of factors.

- 1. Stress causes fingertip temperature to drop several degrees below room temperature.
- 2. A variety of drugs, including tobacco, have an influence on vaso-constriction.
- Vigorous activity increases peripheral circulation, while inactivity decreases circulation.

We will be using the low speed A/D converter that we developed in Chapter 3 along with an analog circuit to interface a thermistor to the Apple II. Figure 6.1 shows the schematic diagram of the

FIGURE 6.1 Schematic diagram of the analog circuitry for the biofeedback temperature monitor.

Number	mber Type +5		-5	GND
ICl	AD580	1		3
IC2	CA3140T	7	4	

analog circuitry. This design uses a thermistor, a device whose resistance is a function of its temperature, in one leg of a bridge circuit. Bridge circuits allow us to detect small changes in resistance by measuring imbalance in the bridge with a differential amplifier.

They are usually small in size, rugged, and they demonstrate the reliability and extended life common to semiconductor products. By using appropriate values of resistance in the bridge circuit, small changes in temperature can be made to produce large changes in output voltage. Since the output voltage is amplified by a differential amplifier (see Appendix B), there will be little problem of noise being introduced into the measurements.

Looking at Figure 6.1, IC1 is a voltage regulator which provides a stable reference voltage to the bridge circuitry. The output voltage from IC1 has been reduced to minimize temperature variations that might occur as a result of self-heating in the thermistor. Such variations, appearing as a slow drifting of the output signal, are undesirable. IC2 is a high gain, differential amplifier that is used to measure the difference between voltages V1 and V2.

Once you have built the analog circuit, you should make the following adjustments and voltage checks:

- 1. The voltage at pin 2 on IC1 should be equal to +2.5 volts.
- Short the points labled V1 and V2 together and adjust R1 until the voltage at E1 is equal to 0 volts. This ensures that the output of the differential amplifier will be equal to 0 when the inputs are equipotential.
- 3. Remove the short from the points labled V1 and V2, hold the thermistor in your mouth for one minute, and adjust R2 (the temperature calibration adjustment) until the output voltage, E1, is equal to +1.07 volts. You should realize that we are going to be interested in relative changes in temperature and not in absolute values of temperature, so calibration will not be precisely performed.
- 4. Connect the output, E1, to the input of the A/D converter. Load and execute BASIC program 1 (see Listing 3.3). The video display should indicate that you are measuring a voltage that increases when you hold the thermistor between your fingertips and decreases when you let go of it.

5. Load and execute BASIC program 2 (see Listing 6.1 and Figure 6.2). You should see temperature plotted as each sample is taken. The plot should move toward the top of the screen for increases in temperature and toward the bottom of the screen for decreases in temperature. Figure 6.3 shows a data plot that results from first putting the thermistor into, and then taking the thermistor out of, the author's mouth. Notice how the temperature of the thermistor goes below the room temperature as a result of evaporation.

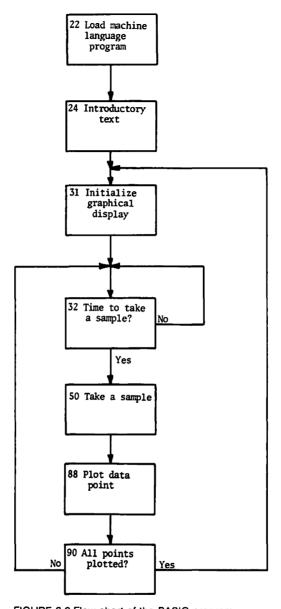

FIGURE 6.2 Flow chart of the BASIC program.

Figure 6.4 shows a diagrammatic representation of the experimental setup. You should tape the thermistor to the index finger on your dominant hand (the hand you write with). You will "see" temperature changes which are too small for you to detect, but

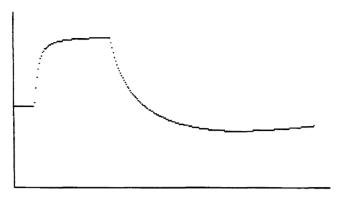

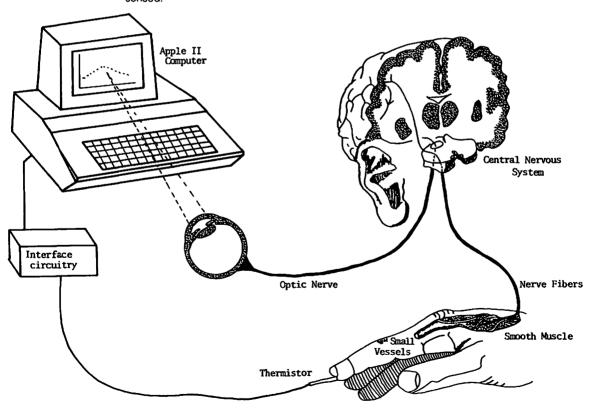

FIGURE 6.3 Graphic display resulting from placing the thermistor in the author's mouth and then removing it.

FIGURE 6.4 Diagrammatic representation of temperature feedback. The electronic measuring system informs the subject of temperature changes so small that they are normally not sensed.

which are easily detected by the thermistor. The graphic display on the CRT will serve as the feedback link to your central nervous system.

First seat yourself in a comfortable chair and, once you are relaxed, imagine that your hand has been placed in hot water. With some practice, you should be able to precisely control an increase or decrease in temperature. Within a few minutes you should be able to raise or lower your temperature one or two degrees merely by "telling" yourself to raise or lower your finger temperature. After some practice, you should be able to increase that variation to ten degrees.

You may want to monitor your temperature while watching a television program, or try taping the thermistor to another part of your body—such as your face—to see how vasoconstriction affects skin temperature in different locations.

HEART RATE

Heart rate changes as a function of many factors. Emotions such as anger and excitement cause an increase in heart rate. Emotions such as fear and grief cause a decrease in heart rate. The body has several regulatory mechanisms which monitor the concentration of carbon dioxide in the blood and the distention of blood vessels, and adjust heart rate to maintain cardiovasular system parameters within acceptable limits. We normally do not think of regulating our heart rate, primarily because there is not an obvious pathway for feedback. However, we can use an electronic measuring system to allow us to monitor our heart rate and to allow us to investigate normal responses to such things as breathing and relaxation.

We can conveniently get an indirect measurement of heart rate by using a system called photoplethysmography. Light can easily be transmitted through capillary beds existing in the earlobe or the fingertip. As arterial pulsations cause the blood volume in the capillary bed to increase and decrease, the amount of scattered, absorbed, and reflected light changes. This phenomena can be used to give us a signal which varies as a function of heart rate. Such a system is sensitive to motion artifacts and performs best when the subject is sitting quietly.

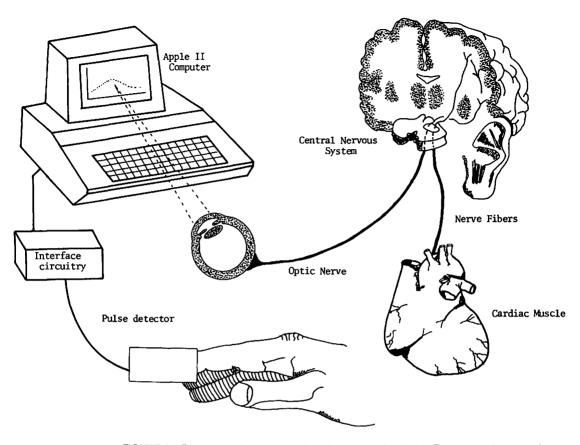

FIGURE 6.5 Diagrammatic representation of heart rate feedback. The electronic measuring system informs the subject of changes too small to be normally sensed.

Figure 6.5 shows a diagrammatic representation of the experimental setup. We will be using the capillary bed in your fingertip to monitor pulsations in blood volume due to contractions of the cardiac muscle. A pulse detector and an analog circuit will be used to detect, filter, and amplify the pulses so that they can be measured by the low speed A/D converter. The computer will then count the pulses and present your heart rate in the form of a graphic display.

Figure 6.6 shows a schematic diagram of the analog circuitry that we will use to interface the pulse detector to the low-speed A/D converter. You should notice that it is a modification of the circuit that we used for measuring skin temperature. This is primarily because a photocell, a device whose resistance changes

Number Type		+5	-5	GND
IC1	AD580	1		3
IC2	CA3140T	7	4	

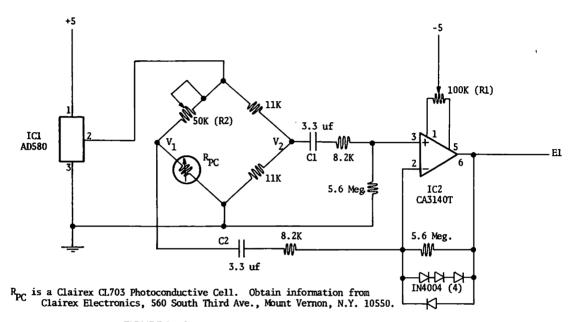

FIGURE 6.6 Schematic diagram of the analog circuitry for biofeedback heart rate monitor.

as a function of the intensity of light falling upon its surface, is being used to detect changes in light passing through the capillary bed in the finger. By putting the photocell into a bridge circuit, small changes in resistance that occur due to small changes in light intensity can be made to produce large changes in output voltage.

Looking at Figure 6.6, IC1 is a voltage regulator which provides a stable reference voltage to the bridge circuitry. Since we are counting pulses and not really measuring a value of resistance, we do not have to be overly concerned about output voltage drift due to internal heating of the photocell. Consequently, we do not have to reduce the output of the regulator, and can thus obtain increased sensitivity from the output of the bridge. IC2 is a highgain, differential amplifier that is used to measure the difference between voltages V1 and V2. Capacitors C1 and C2 are included to

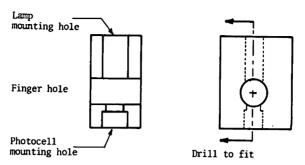

FIGURE 6.7a Position of the photocell relative to the lamp.

block the d.c. component of the amplifier to limit the output voltage, increasing the sharpness of the voltage change that occurs when the heart beats.

You should first concern yourself with the construction of the pulse detector. Figure 6.7a shows a drawing indicating the position of the photocell relative to the light source. The distance between the photocell and the light source will depend on the size of your fingers. To keep this distance to a minimum, make the hole just large enough to fit the smallest finger on your hand, usually the little finger. To get enough intensity from the lamp you will need a 3-volt d.c. supply that can provide about 250 milliamperes. You can use two D-cell batteries connected in series, or you can build a 5-volt supply from Appendix C and use a 10 ohm, 1 watt resistor in series with the lamp. I have shown the latter. To simplify construction as much as possible, I mounted the photocell and the lamp in a small block of wood.

Once you have built the pulse detector and the analog circuit, you should make the following adjustments and voltage checks:

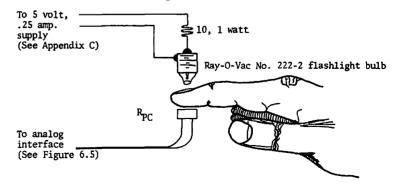

- 1. The voltage at pin 2 on IC1 should be equal to +2 volts.
- 2. Short the points labled V1 and V2 together and adjust R1 until the voltage at E1 is equal to 0 volts.
- 3. Remove the short from the points labeled V1 and V2, and connect the output, E1, to the input of the A/D converter. Load and execute BASIC program 3 (See Listing 6.2). With the lamp disconnected from the lamp supply, you should see the graphics display periodically flashing. When the lamp is connected to its power supply, the flashing should stop.
- 4. Because of the simplicity of the design, you are going to have to develop some skill in positioning your finger in the pulse detector

to ensure consistent operation. We learned in the previous section that cold hands are a good indication of poor circulation. Poor circulation means that blood flow is reduced. This means that the signals from the pulse detector will be small, resulting in erratic operation. If your hands are cold, hold them under warm water for a few minutes. Now, insert your little finger into the pulse detector. Figure 6.7b shows the relative position of the finger with respect to the photocell. As you insert your finger, you should see the display

FIGURE 6.7b Position of the finger relative to the photocell.

- flash in response to the motion of your finger. After you have settled down, you should see the graphics display periodically start to pulse in response to the beat of your heart. Your finger should rest lightly upon the face of the photocell. Too much pressure will stop circulation and cause the display to skip beats.
- 5. Load and execute the BASIC program 4 (See Listing 6.3, Listing 6.4, and Figure 6.8). The program should flash in response to each heart beat, and should display a graphical representation of pulse rate in beats per minute. Figure 6.9a shows a graphical display of the author's resting heart rate.

LISTING 6.4 Machine language routine contained within the BASIC program.

Once you have confirmed that the system is working correctly, insert your finger into the pulse detector and we will learn some things about your cardiovascular system. Remember that the detector is motion-sensitive, so you should assume a quiet sitting position with your arm and hand supported on some surface. The first thing you will notice is that your heart rate is a function of respiration. When you inhale your heart rate decreases. Also, if you hold your breath for several seconds, you should expect to see a decrease followed by an increase in heart rate. The graphical display on the CRT will be used as the feedback path to your central nervous system. You can alter your heart rate by practicing progressive relaxation exercises. The idea behind these exercises is to learn how to relax by sensing the difference between tension and relaxation. Start by assuming a comfortable position. Starting

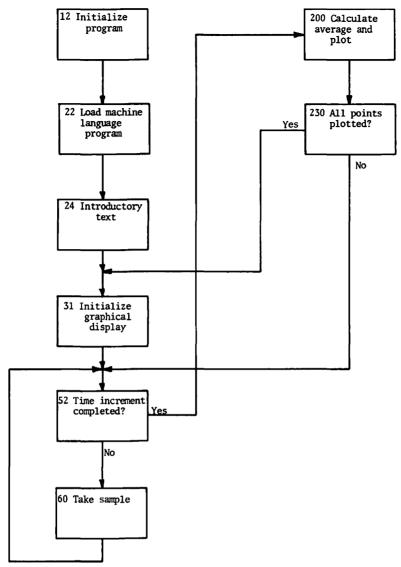

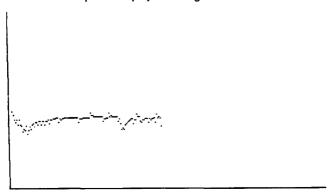

FIGURE 6.8 Flow chart for the BASIC program.

FIGURE 6.9 Graphical display of resting level heart rate.

with the feet, alternately tense and relax your muscles. Suppose you have tensed the muscles in your left leg. When you relax that group of muscles you should feel the leg become limp and heavy. As you progress through this type of relaxation process, your heart rate should decrease, indicating a state of relaxation.

You may want to monitor your heart rate while watching your favorite television program. Sporting events or mystery shows are good candidates for causing your heart rate to significantly increase and decrease. Monitor your pulse rate while you drink a cup of coffee or as you smoke a cigarette. For the more daring individual, you might want to monitor your heart rate as you balance your checkbook at the end of the month.

CONTROLLING A VIDEO PLAYBACK DEVICE

The phrase "one picture is worth a thousand words" illustrates the importance of visual representation of material in the learning process. Educators have effectively used snapshots, slides, filmstrips, and motion pictures to aid students while avoiding some of the problems that might occur from direct contact with the subject being studied. While this media serves a purpose, its effectiveness is limited since the viewing speed and the content of the material is fixed, and there is no simple means of allowing individual students to interact with the viewing device.

In an attempt to increase the personal interaction of teaching systems with the student, slide/audio cassette systems have been developed. These systems have been used successfully for many years as a low-cost supplement to textbook instruction at all educational levels. Using individual viewing screens and head-

phones, the student can view and review such things as sequential anatomical dissections, while listening to a detailed description of what they are seeing.

Television has expanded on slide/audio tape systems by allowing the low-cost presentation of prepared lecture material and permitting live demonstrations of such things as surgical procedures to large audiences. The introduction of the videotape recorder has increased the impact of television by allowing lecture and demonstration materials to be recorded and then played back any number of times. Recently, the less expensive videocassette player has made it possible for students to individually view and review prerecorded lecture material. The intimacy of videocassette presentations is surpassed only by the live classroom lecture where the important ingredient of student-teacher interaction is present.

The availability of low-cost personal computing systems has provided another (and more sophisticated) tool for educators. Computer-assisted instruction (CAI) is a term used for a system in which the computer carries on a predetermined instructional strategy, and permits conversational interaction with the student. Computers are most recognized for their high-speed computational ability. Because of this, computers can be used in real-time simulation of complex physical systems and, when interfaced with a graphic display, the computer can be very effective in assisting students in their understanding of these systems.

While the use of the small personal computer in an educational environment is not a new concept, the use of a personal computer to interactively control a videocassette player is. Videotaped material is abundant and readily available. Often the student will not need to review a complete lecture, but will only be concerned with a specific segment. In a case such as this, the computer can be used to provide a menu from which the student can choose the desired segment. The computer then is responsible for finding the starting point of the desired segment, initiating the PLAY command, and stopping the presentation when the end of the segment is reached. The interaction of the computer and the video device can also be used as a teaching machine where the computer is used to control the presentation of videotaped lectures. At appropriate times, the lecture could be interrupted and questions asked of the viewer. Depending on the response, the

viewer would be allowed to continue, would be supplied with remedial material, or would just be returned to the start of the most recently viewed segment. This provision of immediate feedback is an important part of the system concept and is a particularly strong feature of computer-assisted instruction. Theoretically, this system should have the following advantages over conventional methods of instruction such as a group lecture:

- 1. Students can proceed through material at a rate which is consistent with their ability.
- 2. Correct responses to questions allow additional material to be presented. Incorrect responses cause material to be repeated, or supplementary material to be presented.
- Material presentation can be organized so that special guidance can be given to correct deficiencies in individual educational backgrounds.
- 4. Teaching material can be organized for an optimal sequence of presentation.
- 5. The student is forced to play an active part in the learning process.

The design of the Sony Betamax SL0-320 videocassette recorder makes interfacing the Apple II computer to it a relatively easy task. Table 7.1 shows the control, status, and timing lines that are available from the interface connector on the back of the Betamax. During the recording process, a timing signal is recorded onto the videotape. This timing signal, available on pin 15 of the Auto Search control unit interface connector, can be sampled by the computer and used to index the tape to any relative location. There are two status signals that are available at the interface connector: one signal (CASSETTE IN*) indicates when the video-

TABLE 7.1 Betamax status and control signals available through the pins that connect the recorder to the RM-300 Auto Search control unit.

Betamax Connector Pin	Signal	Source/ Destination
ONI-20 ONI-7 ONI-11 ONI-8 ONI-13 ONI-12 ONI-15	BEGINNING OF TAPE* CASSETTE IN* REWIND* STOP* PLAY* FAST PORWARD* COUNT*	Status signal from Betamax Status signal from Betamax Command signal to Betamax Command signal to Betamax Command signal to Betamax Command signal to Betamax Timing signal from Betamax

cassette has been inserted into the player and the other signal (BEGINNING OF TAPE*) indicates when the videocassette tape has been fully rewound. These signals were not used in the system that is being described, but certainly could be used if a modification of the system concept makes it desirable. Four control lines (STOP*, PLAY*, FAST FORWARD*, and REWIND*) are also available at the interface connector, and are used to indicate to the Betamax the desired mode of operation.

Figure 7.1 shows the Betamax to Apple II interface in schematic form. The left side of the schematic shows connections

made to the Betamax through the RM-300 Auto Search control unit connector, while the right side of the schematic shows the connections made to the Apple II through the I/O bus connector. Line 15 (COUNT*) from the Betamax carries the timing signal formatted onto the videotape. This signal is divided by a factor of sixty by the combined action of integrated circuits IC1 (SN7490) and IC2 (SN7492). IC3 (MC14512) is an eight-channel data selector which is used to connect the divided timing signal to the Apple II data line seven (D7). Increased channel sampling capability was incorporated so that the two status lines from the Betamax, or other user-defined status lines, could be sampled if so desired. Data line D7 was chosen because its state is easily tested by rotating its contents into the carry bit. Integrated circuit IC7 (MC14514) is a 4-16 line decoder latch which is used to selectively turn on one of the four transistors, thus causing the Betamax to enter either the PLAY, the REWIND, the FAST FORWARD, or the STOP mode. Table 7.2 shows the function that will be accessed for a given BASIC statement or a given machine language command. Provision was made for storing the computer program on a beginning segment of the videotape. To record the program on the videotape you should amplify the output of the computer going to the cassette recorder during a SAVE operation by a factor of ten. Figure 7.2 shows a simple circuit for doing this (refer to Appendix B for a description of the circuit). In order for the audio to be recorded, you will have to provide both the audio signal and a video signal. IC12 (MC14528) is a dual monostable multivibrator configured so that it switches the Betamax into the PLAY mode

TABLE 7.2 Software commands, in both BASIC and 6502 machine language, necessary to activate the Betamax control lines.

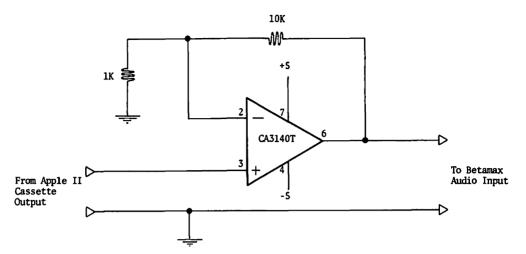

FIGURE 7.2 Operational amplifier circuit for recording Apple II cassette output into the video tape.

when LOAD is entered from the Apple II keyboard, and switches it into the STOP mode when the program has been loaded. IC11 (CA3140T) buffers the audio output from the Betamax to the Apple II cassette audio input during the program load operation.

Once you have completed construction of the interface, you should perform the following tests to make sure that it is working correctly:

- For each of the Betamax control functions listed in Table 7.2, execute the two BASIC commands associated with the control function. The Betamax should respond in an appropriate manner.
- 2. Load the Apple II with the test program that is shown in Listing 7.1. Using a prerecorded video tape placed in the cassette player, execute the program. The program should exercise the following player functions:

FAST FORWARD PLAY STOP REWIND STOP

3. If everything functions correctly up to this point, try storing the test program on the beginning segment of a blank videocassette. Remember to connect the audio cables from the Apple II to the Betamax and back again. Remember also to provide some type of video

signal to the Betamax during the recording process. If you now rewind the tape and enter LOAD, you should see the Betamax begin to play, and the computer should sound a tone, indicating that a normal load is taking place.

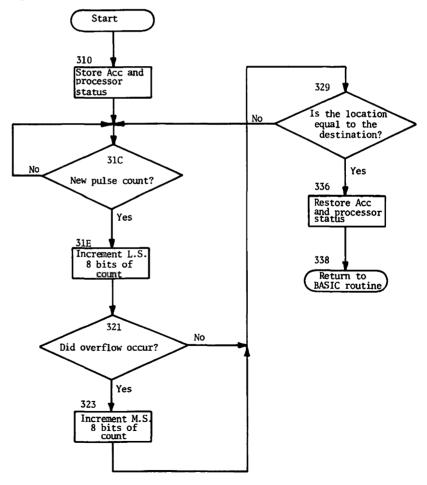

The software portion of the controller was written in two parts:

 Two machine language routines were written to count the pulses coming from the timing track stored on the videotape, and to determine when the desired destination on the videotape had been

- reached. One routine is used when the tape is moving forward and the other routine is used when the tape is moving backward.
- A routine was written in Applesoft BASIC to load the desired tape destination, and to control the operational mode of the cassette player.

Figure 7.3 shows a flow chart of the machine language routine which is used when the tape is moving forward, and Listing 7.2 shows the actual program with comments. Figure 7.4 shows a flow chart of the machine language routine which is used when

FIGURE 7.4 Flow chart of the machine language routine for decrementing and comparing the videotape location count.

the tape is moving backward, and Listing 7.3 shows the actual program with comments. Upon entering either routine, the processor status and the accumulator are pushed onto the stack. The line containing the pulses from the timing track on the video tape is then sampled until it has been determined that the tape has moved a distance equal to one pulse width. A register containing two 8-bit words is then either incremented or decremented depending on whether the tape is being moved forward or in reverse. The contents of this register is then compared to the contents of a register containing the two 8-bit words representing the destination. If the two registers are equal, the tape has reached its destination and the computer returns to the BASIC routine. If the two registers are not equal, the program goes back to wait for the next timing pulse.

Figure 7.5 shows a flow chart of a BASIC routine which has been used for demonstration purposes, and Listing 7.4 shows the actual program with comments. There is an initial decision point at line 232 where a student decides whether he or she needs to watch the whole program or just selected parts. After viewing a segment of instructional material, the student is asked a series of

DATA ANALYSIS TECHNIQUES

CURVE FITTING

The observation of naturally-occurring phenomena is often the basic approach of a scientific researcher. Data are recorded as a function of some dependent variable (a parameter that is not a function of the phenomena that is being observed) and the researcher then draws conclusions based on the relationship between the two variables. The first step that usually occurs after the data have been gathered is the posing of question: What mathematical formula best describes the relationship between the two variables?

Linear Regression

The simplest relationship that two variables could have is a linear relationship, that is, the dependent variable and the independent variable would increase or decrease with a one-to-one relationship. When a linear relationship occurs, the dependent variable can be expressed as a function of the independent variable by the following equation:

$$y = A x + B$$

where A and B are constants (8.1)

The following program will find values for A and B which will give the closest agreement between the experimental data and Equation 8.1. The technique that will be used is called linear regression by the method of least squares.

Listing 8.1 shows the program with comments. The program expects to receive x and y pairs of data. When all the values have been entered, the program computes the coefficient for Equation 8.1 and calculates a coefficient of determination to give a relative indication of the goodness of fit. Once the equation has been generated, you may predict values of y for given values of x.

EXAMPLE A forgetful electrical engineering professor wakes up one morning and thinks that he might have a fever. A search through his medicine cabinet produces an oral thermometer, but it slips through his fingers and falls to the floor, breaking into a thousand pieces. Disgusted with himself, he suddenly realizes that he has an outdoor thermometer which is calibrated in degrees Fahrenheit, but it is much to big to fit in his mouth. He remembers that the skin-temperature biofeedback project he built has a thermistor probe, but that it is not calibrated. He suspects that the probe is linear and that the relationship between the output voltage from the interface and temperature might be equal to Equation 8.2. He knows that if he could get a few data points he could run the linear regression program and solve for the coefficients of the equation:

$$T = aV + b (8.2)$$

He places both the thermometer and the thermistor probe into a sink of warm water and records the following data points:

V(volts)	1.055	1.044	1.014	.984	.974	.943	
T(F)	104	103	100	97	96	93	

Find the values for a and b? What is the coefficient of determination? If the professor's temperature is equal to 1,006 volts, should he be worried?

Exponential Regression

Another common relationship between data pairs is described by an exponential curve. When such a relationship exists, the dependent variable can be expressed as a function of the independent variable by an equation having the following form:

$$y = A e^{Bx} ag{8.3}$$

The following program will find values for A and B which will give the closest agreement between the experimental data and Equation 8.2. The technique that will be used is called exponential regression by the method of least squares.

Listing 8.2 shows the program with comments. The program expects to receive x and v pairs of data. When all the values have been entered, the program computes the coefficients for Equation 8.2 and calculates a coefficient of determination to give a relative indication of the goodness of fit. Once the equation has been determined, you may predict values of y for given values of x.

EXAMPLE Realizing a bargain when he saw one, Fred bought several large capacitors at the local flea market for a very low price. Unfortunately, these capacitors were unmarked. Fred knows that a capacitor, being charged through a series resistor from a fixed voltage source, will exponentially increase in voltage as time increases. By knowing the value of the series resistor, and measuring the voltage across the resistor as a function of time, he should be able to use the exponential regression program to determine the value of the capacitance. Using his high school electronics text, Fred determines that the voltage across the series resistor will be equal to the following equation:

Getting out the high speed A/D converter that he built in Chapter 3, Fred gets ready to prove to himself that the capacitors really were a bargain. Fred sets the sampling rate at one sample per second and obtains the following set of data points:

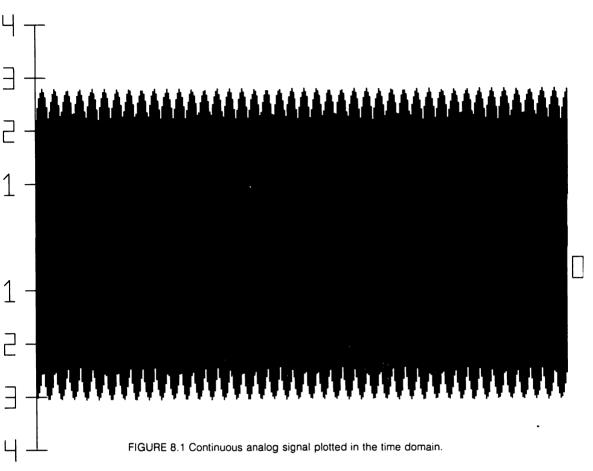

ŧ	Λ	1	2	3	4	5
L	U	1	4	3	-	J
37	5	10	7	25	.109	042
v	J	1.5	• /	,20	.109	.042

Find the values for a and b in Equation 8.4 and calculate the capacitance of Fred's capacitor. If he needs ten farads for his plasma discharge generator, will he be able to use this particular capacitor?

Fast Fourier Analysis

LISTING 8.2 (Continued)

The sounds that your ears receive are comprised of many individual frequencies which are summed together to form a complex waveform which gives the sound its characteristic quality. It is possible to take an arbitrary continuous signal, expressed in the time domain, and break it up into a series of individual frequencies. The magnitude of this spectrum at different frequencies is a measure of the frequency content that comprises the original signal. The concept of spectrum finds many practical applications in many varied disciplines including waveform analysis of music, frequency content of muscle voltages, vibrational characteristics of mechanical systems, and so on. Figure 8.1 shows a plot, in the

time domain, of a complex analog waveform. It would be very difficult to come to any conclusions regarding the spectral content of the signal by just visually analyzing it. Figure 8.2 shows the same waveform transformed into the frequency domain by a fast Fourier transform (FFT). You can easily observe a small d.c. component at the far left of the plot and make the statement that the complex waveform contains a single high-frequency signal. In fact, Figure 8.1 is just the plot of a 200 Hz sine wave.

Listing 8.3 shows a program written in Applesoft which performs the fast Fourier routine. The program first gets the data file that we created with the high speed A/D converter that we described in Chapter 3. The FFT routine then mathematically separates the complex waveform into the sum of a number of

FIGURE 8.2 Signal from Figure 8.1 analyzed by the fast Fourier transform and plotted as a function of frequency.

discrete frequencies, and plots the magnitude of each frequency component. The frequency spacing between each component is a function of the digitization frequency and the number of points that you have in the routine process. You then have to decide how many of those points you wish to process with the FFT. Using a larger number of points results in greater resolution but requires more processing time. For example, 512 points requires 16 minutes, 256 points requires 8 minutes, and 128 points requires 4 minutes. You can calculate the frequency spacing between each component with Equation 8.5.

```
F = 1/(t*N) Hz

where F = the distance between each component
t = the time increment between samples
N = the number of processed points

(8.5)
```

If we were sampling an input signal at a rate of 1000 Hz, then t would be equal to .001 seconds. If we then decided to process 512 points, we would expect the distance between components to be equal to 1.95 Hz. This means that if we had digitized a 19.5 Hz sine wave, we would expect to see a peak in the magnitude of the output at the 11th point (the magnitude of the d.c. component occupying the first point).

You can do several things to enhance the utility of these routines:

1. Write programs to plot both the complex waveform and the Fourier transform with the digital plotter developed in Chapter 5.

2. Convert the BASIC program shown in Listing 8.3 into a machine language routine to greatly decrease the time spent processing the data.

To help assure yourself that you have entered the program correctly, I have included a simple program which generates a perfect 100 Hz sine wave and stores it in memory. After loading the main program, key in the following BASIC statements.

```
80 REM

90 Y=24830:T=0

91 FOR Z=0 TO N-1

92 Y=Y+2:X=1+SIN(2*3.14159*100*T)

94 T=T+7.8125E-4

95 POKE Y, 3:POKE (Y+1),100*X

96 NEXT Z

203 REM
```

If everything is working correctly, you should observe a peak in magnitude at the eleventh output.

The following four figures show the results of taking the FFT of 512 points of data from audio data digitized at a rate of 1000 samples per second. Figure 8.3 shows the spectrum of a violin solo. Notice how there are very distinct harmonics displayed. Figure 8.4 shows the spectrum of the speaking voice of a male radio announcer. Notice how the spectrum is rich in low frequency content. Figure 8.5 shows the spectrum of the singing voice of a popular singer who was holding a high clear note when the data was collected.

FIGURE 8.3 Fourier transform of violin solo.

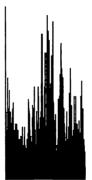

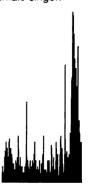

FIGURE 8.5 Fourier transform of the voice of a female singer.

APPENDIX A: CONSTRUCTION TECHNIQUES

Before you start to build, you should have some feeling for the construction options that are available to you. This will allow you to use appropriate construction techniques for specific circuits that you will be building. I am not going into a lot of detail concerning the actual construction process involved in each option, since this has been covered in detail in other publications. However, based on my personal experience, I will summarize the advantages and disadvantages of each process.

If you need to build ten or more boards having the same circuit configuration, you might want to have a custom circuit board constructed. There are usually a number of small companies in any large metropolitan area which can perform this service. Costs will run about \$500 for the circuit board layout and about \$20 apiece for each circuit board. The cost is directly pro-

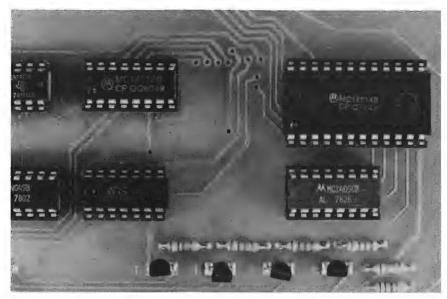

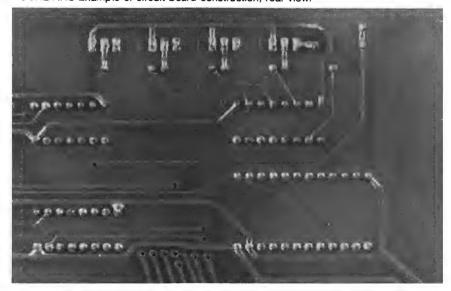

FIGURE A.1a Example of custom circuit board construction, front view.

portional to the complexity of the circuit design. Disadvantages include waiting about four weeks for the boards to be fabricated, the cost of fabrication, and the loss of modification flexibility. Advantages include decreased construction time for each circuit, increased reliability of operation, and an obviously professional appearance. Figures A.1a and A.1b show examples of this type of construction.

If you need to construct a single circuit that is very simple, I would recommend Vector board and push-in, solderable terminal type construction. Figure A.2 shows an example of this type of construction. Vector board (Vector Electronics Company, Inc., Sylmar, California 91342), Vector pins, and a tool to insert the pins can be purchased at your local electronics store. It is the least expensive method of construction and I have used it with success. However, this type of construction sometimes results in undesirable oscillations caused by output signal wires being in close proximity with input signal wires. Another possible problem is the introduction of high frequency noise, generated by the digital circuitry, into power supply lines. I would discourage its use with DIP packaged integrated circuits unless you are quite proficient with a soldering iron.

If you are adventurous, and have an abundance of time, you should consider laying out the foil pattern and then etching your own circuit boards (Circuit Board Etching, M. W. Houser, Davis Publications, New York, New York 10017, January 1981). This

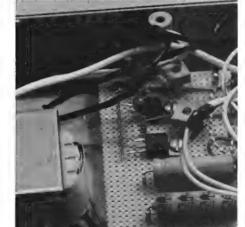

FIGURE A.2 Example of Vector board construction.

process is limited to relatively simple circuits, but the finished boards are inexpensive to produce and will result in a circuit having mechanical properties which are superior to hand-wired boards.

If the circuit is complex or if you are planning on doing several construction projects over a period of time, I would recommend that you develop your capability to produce wirewrapped circuits (Wire-Wrapping Techniques, W. Sikonowiz, Davis Publications, New York, New York 10017, January 1981). This type of construction is fast and economical, and it results in circuits that will perform reliably in a variety of applications. Figures A.3a and A.3b show examples of this method of construction. Wire-wrapping allows the builder to use point-to-point construction techniques and still obtain a circuit board which is rugged enough to be put into practical use. Construction proceeds relatively fast and corrections can be easily made. While there is an initial investment, the individual cost of a finished board is comparable to other techniques.

Putting your finished circuit into a cabinet adds a great deal to the personal satisfaction that you will receive from completing

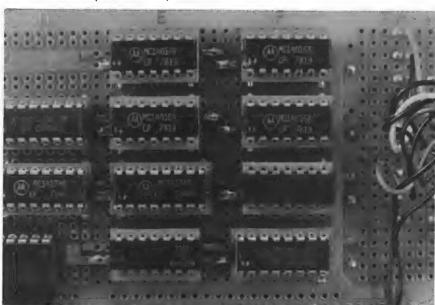

FIGURE A.3a Example of wire-wrap construction, front view.

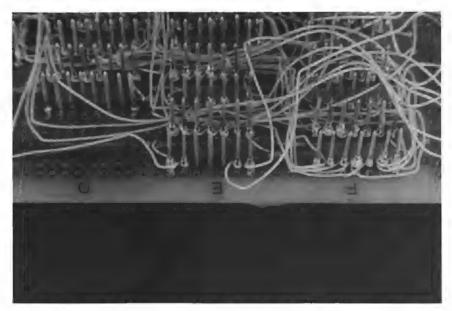

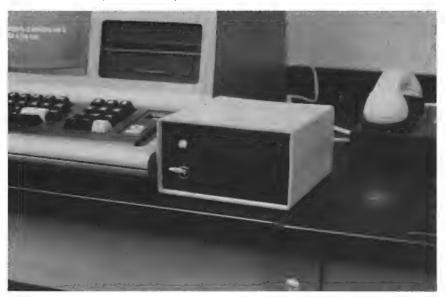

FIGURE A.3b Example of wire-wrap construction, rear view.

the project. Plastic boxes are very easy to work with and are quite adequate for the types of projects that I will be describing. Figures A.4a and A.4b show examples of this type of finished construction.

FIGURE A.4a Example of finished product.

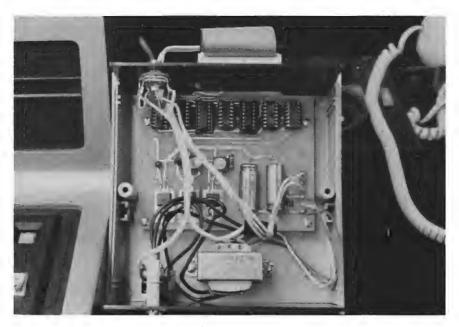

FIGURE A.4b Example of finished product.

APPENDIX B: OPERATIONAL AMPLIFIER THEORY

The operational amplifier (op amp) will be one of the most important tools you will have at your disposal when it comes time to interface some type of transducer to an A/D converter. Since most operational amplifiers have one output and two input ports, we can consider them to be a general three-port device. Their basic function is to amplify the difference between the two signals which are applied to the input ports. The amplified difference then appears at the output port. The relationship between the output voltage and the input voltages is dependent on the sign and magnitude of feedback which is supplied by the output to one or more of the inputs. As a result of feedback, we can configure our circuit to add, subtract, multiply, integrate, differentiate, compare, rectify, filter, and perform current-voltage conversion.

There are three general characteristics of the operational amplifier that make it a useful tool:

- 1. It has very high gain from either of the two input ports to the output port.
- 2. The input impedance at each input port is very high and the output impedance is very low.
- 3. It has very low gain when the same signal is applied to both input ports at once. Consequently, the amplifier is most sensitive to the voltage difference between the two inputs rather than the voltage difference between either input and ground. This allows the amplifier circuit to disregard many signals which would be classified as noise and to respond only to the signal coming from the transducer.

Since many of our projects deal with small magnitude signals, we will need to provide amplification, and possibly filtering, to increase our ability to resolve and accurately display these signals. The operational amplifier will allow us to combine a fifty-cent integrated circuit with a knowledge of Ohm's law, and become proficient at designing small signal amplifiers for our interface projects.

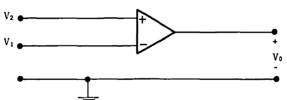

FIGURE B.1 Op-amp circuit symbol. A voltage at V_1 , the inverting input, is greatly amplified and inverted to yield an out-of-phase output at V_0 . A voltage at V_2 , the noninverting input, is greatly amplified to yield an in-phase output at V_0 .

Figure B.1 shows the operational amplifier circuit symbol. You should notice the two input terminals and the single output terminal. One of the input terminals has a negative sign associated with it (the inverting input) and one of the inputs has a positive sign associated with it (the noninverting input). There are two basic rules which we will be using to design and analyze op amp circuits:

- 1. When the op amp is operating in a linear region, the two input terminals are at the same voltage.
- 2. There can be no flow of current into either of the input terminals.

Armed with these two constraints we can begin our discussion of specific amplifier circuits.

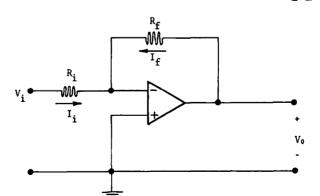

INVERTING AMPLIFIER

Figure B.2 shows a basic inverter circuit which is widely used for instrumentation purposes. The input impedence for this configuration is approximately equal to the magnitude of resistor R_i . Note that a portion of the output signal is fed back through resistor R_i to the negative input of the op amp. Reviewing the two rules which we have previously discussed, we know that both the positive and the negative inputs are at the same potential, which for this circuit is equal to 0 volts. We also know that the current flowing into or out of each of the two input terminals has to be equal to 0. Using Kirchhoff's current law we can write the following equation:

$$\mathbf{I}_{i} + \mathbf{I}_{j} = 0 \tag{B.2a}$$

 $V_0 = -\left[\frac{R_f}{R_i}\right]V_i$

FIGURE B.2 Simple resistive inverting amplifier. A voltage at V_i , the inverting input, produces a voltage at the output, V_0 , which is a function of the values R_i and R_f .

Using Ohm's law we can write the following two equations:

$$V_i - R_i I_i = 0 \tag{B.2b}$$

$$V_0 - R_t I_t = 0 \tag{B.2c}$$

Solving equation B2.2b for I_i , solving equation B2.3a for I_i , and then substituting these two values back into equation B2.2a, we obtain equation B.2d:

$$(V_i/R_i)+(V_o/R_i)=0$$
 (B.2d)

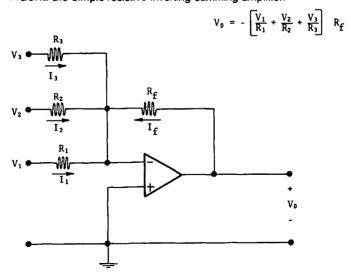

The voltage gain (K) for the circuit can then be written as follows:

$$K = V_o/V_i = -(R_f/R_i)$$
 (B.2e)

Figure B.3 shows a modification to the basic inverter circuit which allows us to add several input voltages together. Remembering our two basic rules, we know that the inverting and the noninverting input terminals are at the same potential and that there can be no current flowing into or out of either of these terminals. Summing currents at the inverting terminal we obtain the following equation:

$$I_1 + I_2 + I_3 + I_4 = 0$$
 (B.3a)

FIGURE B.3 Simple resistive inverting summing amplifier.

Using Ohm's law we can write equations for these currents in terms of the input and output voltages.

$$I_1 = V_1/R_1 \tag{B.3b}$$

$$I_2 = V_2/R_2$$
 (B.3c)

$$I_3 = V_3/R_3 \tag{B.3d}$$

$$\mathbf{L} = \mathbf{V}_{o}/\mathbf{R}, \tag{B.3e}$$

Substituting these equations back into equation B.3a we get equation B.3f:

$$(V_1/R_1)+(V_2/R_2)+(V_3/R_3)+(V_0/R_f)=0$$
 (B.3f)

Solving for the output voltage, expressed as a function of the input voltages and the resistance values, we get the following equation:

+
$$V_0 = (R_f/R_1)V_1 + (R_f/R_2)V_2 + (R_f/R_3)V_3$$
 (B.3g)

NONINVERTING AMPLIFIER

Figure B.4 shows an amplifier configuration which is sometimes called a *voltage follower* because the output voltage is the same polarity as the input voltage. This circuit is useful because the

FIGURE B.4 Simple resistive noninverting amplifier. A voltage at V_i , the noninverting input, produces at the output V_o , which is a function of the values R_i and R_f .

$$V_{0} = \left[1 + \frac{R_{f}}{R_{i}}\right] V_{i}$$

$$V_{i} = \left[1 + \frac{R_{f}}{R_{i}}\right] V_{i}$$

$$V_{i} = \left[1 + \frac{R_{f}}{R_{i}}\right] V_{i}$$

input impedance is extremely large; therefore, the circuit does not draw much current from the circuit that is attached to its input. Again we have a circuit that has a portion of the output signal fed back to the inverting input through the feedback resistor R_f. The two rules which we have discussed state that the voltage at the inverting input will be equal to the voltage at the noninverting input, and that there will be no current flow into or out of either input terminal. Using Ohm's law we can write an expression which will relate the magnitude of the voltage at point a to the output voltage Vo.

$$V_a = V_o R_i / (R_i + R_f)$$
 (B.4a)

We know that $V_a = V_1$, and if we substitute this back into equation B.4b we get the following equation:

$$V_i = V_o R_i / (R_i + R_f)$$
 (B.4b)

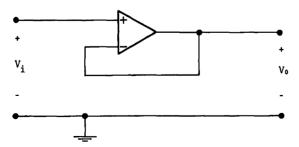

By rearranging this equation we can obtain an expression which gives the voltage gain of the circuit as a function of the resistors R_i and R_f .

$$K = V_o/V_i = 1 + R_f/R_i$$
 (B.4c)

By looking at equation B.4c, you should be able to predict what happens to the voltage gain as a resistor R_i becomes very large. Figure B.5 shows a circuit diagram where this resistance has been

FIGURE B.5 Simple unity gain voltage follower.

$$V_0 = V_i$$

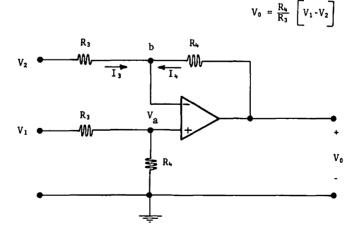

set equal to infinity (open circuit). This is a special circuit called the unity-gain voltage follower. Remembering that the voltages at the two input terminals have to be equal to one another, we can see that the output voltage is forced to be equal to the input voltage. This circuit is often used to provide impadence transformation from very high at the input to very low at the output.

DIFFERENTIAL AMPLIFIER

We found that we could add two or more signals together by using the inverting summing amplifier configuration. We will now take a look at a circuit which will allow us to subtract one signal from another. Figure B.6 shows an operational amplifier used as a differential amplifier. One of the advantages to using this circuit is that the circuit subtracts voltages applied to both inputs therefore producing an output only when the input voltages are not equal. This is useful when we have a balanced input circuit and need to reduce noise which is common to both of the inputs. Remembering that the voltage at the inverting input has to equal the voltage at the noninverting input and that no current can flow into or out of either terminal, and using Ohm's law, we can write

FIGURE B.6 Simple resistive differential amplifier. This circuit is configured so that the output voltage, V_0 , is equal to the difference of the input voltages, V_1 and V_2 , multiplied by a constant which is a function of the resistors R_3 and R_4 .

an equation for the voltage at point a in terms of the input voltage V_1 :

$$V_a = V_1 R_4 / (R_3 + R_4)$$
 (B.6a)

This voltage has to be equal to the voltage at point b. We also know that the following relationship exists between current I_a and current I_a :

$$I_3 + I_4 = 0$$
 (B.6b)

We can write the following equations to relate the output voltage to the input voltages:

$$I_3 = (V_2 - V_b)/R_s$$
 (B.6c)

$$I_4 = (V_o - V_b)/R_4$$
 (B.6d)

Substituting equation B.6a into equations B.6c and B.6d and then substituting these equations back into equation B.6b gives the following result:

$$V_o/R_4 = (V_1 - V_2)(1/R_3)$$
 (B.6e)

Rearranging this equation gives us an equation which relates the output voltage to the input voltages as a function of the resistance values.

$$V_o = (R_4/R_3)(V_1 - V_2)$$
 (B.6f)

INTEGRATING AMPLIFIER

The integrating amplifier (see Figure B.7) is a circuit whose gain varies as a function of frequency making it different from the circuits we have previously considered. Detailed analysis would show that the output voltage will be related to the magnitude and the frequency of the input voltage by the following equation:

$$V_o/V_i = -1/(wRC)$$
 (B.7a)

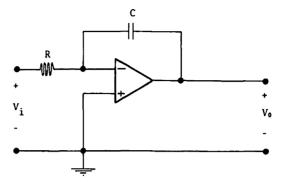

FIGURE B.7 Simple integrating amplifier. The time constant of this circuit is directly related to the product of resistor R and capacitor C.

This equation can also be written as a function of time; this may actually be a more familiar representation for the majority of readers:

$$V_{o} = -1/RC \int_{t_{i}}^{t_{2}} V_{i} d_{t}$$
 (B.7b)

Figure B.8 shows an integrator which has had a resistor added in parallel with the capacitor. This provides us with a circuit, called a low pass filter, which is useful for attenuating high frequency noise. As with the integrator, the frequency response is given by the ratio of feedback to input impedance. However, at low frequencies the circuit behaves like an inverter because the impedance of capacitor C is large when compared to the resistor R_2 . At higher frequencies, the circuit behaves like an integrator because the impedance of C becomes smaller than R_2 . Equation B.8a expresses the gain of this circuit as a function of frequency:

$$V_o/V_i = (R_2/R_1)(w/R_2C)(1/1 + w/R_2C)$$
 (B.8a)

At low frequencies this equation reduces to the following equation which will be recognized as the equation for the simple inverting amplifier:

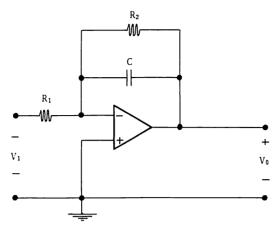

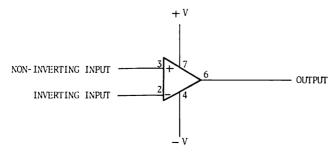

FIGURE B.8 Simple low-pass filter. The low frequency gain of the circuit is a function of R_1 and R_2 . The 3_{db} corner frequency is determined by the values of capacitor C and resistor R_2 .

$$V_{o}/V_{i} = -(R_{f}/R_{i})$$
 (B.8b)

At high frequencies equation B.8a will reduce to equation B.7a. When a circuit designer needs to limit the frequency response of a wide-band amplifier, there is no need to add a separate stage but only to add the correct size capacitor to the existing circuit.

There are many operational amplifiers which you could use in the circuits which we have discussed. An op-amp which is commonly available, low in cost, and easy to use is the 741. This is a general purpose device which provides output short circuit protection, internal phase compensation, and latch free operation. Another device which is readily available is the CA3140. This operational amplifier differs from the 741 by having MOS/FET input stages which provide high input impedance. The pin configuration for both of these devices is shown in Figure B.9.

FIGURE B.9 Pin assignment for the 741 and CA3140T operational amplifiers.

APPENDIX C: POWER SUPPLIES

The widespread availability of three terminal regulators makes the design and construction of power supplies for digital and analog circuits almost a simple task. In the past, power supplies were generally made from a number of discrete components. Today, advancements in fabrication techniques related to monolithic semiconductors have enabled a number of discrete components to be incorporated into a single chip. This has resulted in a series of low-cost positive and negative regulators which are extremely easy to use, and difficult to abuse. Monolithic voltage regulators usually have a series pass transistor power control element, a reference source, and current overload protection all on the same chip. As a result of this, no adjustments are required to set up the output voltage, and it is virtually impossible to destroy the regulator.

Figure C.1 shows a schematic of a+5 volt power supply that can provide up to .5 amperes of current with adequate heatsinking.

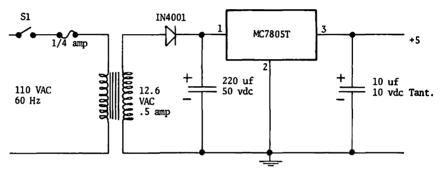

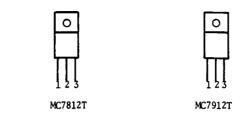

FIGURE C.1 Positive 5-volt power supply.

Figure C.2 shows a schematic of a +12 and -12 power supply that can provide up to .5 amperes of current with adequate heatsinking.

Once you have constructed either of the supplies, you should check to make sure that the output voltage is what you were expecting it to be. You should be concerned about the following:

- 1. Treat the 110-volt line voltage with care.
- 2. Make sure that the polarity of the filter capacitators is correct.
- 3. Make sure that the polarity of the diodes is correct.
- 4. The positive and negative regulators do not use the same pin configuration. Be sure that you have used the correct pins for input, output, and ground.

RICHARD C. WALLEREN

interface projects for the apple II

This practical manual explains how computer users can better utilize the computational and control capabilities of their personal computer.

Written for the Apple II user with some previous computing experience, INTERFACE PROJECTS FOR THE APPLE II provides a series of complete interface projects that are easily built and enable you to discover the computer's capabilities as the project is constructed.

Inside these pages you'll find dozens of fully tested hardware projects—plus all the necessary interfacing software—that you can use as is or simply modified to meet your specific needs. It includes important information on:

- review of data transfer formats
- digital and analog conversions with the Apple II
- serial applications on the Apple II
- biofeedback
- how to control a video playback device
- data analysis of sampled signals
- construction techniques
- power supplies
- and more.
